THE LANCET.

A Journal of British and Foreign Medicine, Surgery, Obstetrics, Physiology,
Chemistry, Pharmacology, Public Health, and News.

IN TWO VOLUMES ANNUALLY.

VOL. CCVIII.

VOL. I. FOR 1925.

ONE HUNDRED AND THIRD YEAR.

EDITED BY
SIR SQUIRE SPRIGGE, M.A., M.D. CANTAB., F.R.C.S. ENG.,
AND
EGBERT MORLAND, B.Sc., M.B. LOND., M.D. BERNE.

LONDON
PRINTED BY HAZELL, WATSON & VINEY LD., 52, LONG ACRE, W.C. 2, AND PUBLISHED BY THE PROPRIETORS,
AT THE OFFICES OF "THE LANCET," No. 423, STRAND, AND No. 1, BEDFORD STREET, STRAND.
MCMXXV.

INDEX TO VOLUME I., 1925.

☞ *Readers in search of a given subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate but nearly synonymous headings—such, for instance, as Brain and Cerebral, Heart and Cardiac, Liver and Hepatic, Child and Infant, Goitre and Thyroid, Diabetes, Glycosuria and Sugar, Eye, Ophthalmic, and Vision, Lunacy and Mental Disease, Arsenobenzol and Salvarsan, &c., &c., and that regional headings are more frequently used than pathological. Institutions and Corporations with the right to the prefix Royal will be found under that prefix, with the exception of Hospitals, which will be found under that heading; and Medical Societies, which are separately indexed under Societies. All Universities are indexed under the word University. (A.) = Annotation, (C.) = Correspondence, (C.M.P.) = Conduct of Medical Practice. (N.I.) = New Inventions, (L.A.) = Leading Article, (M.L.) = Medico-legal, (M.T.T.) = Modern Technique in Treatment, (O.) = Obituary, (P.I.) = Parliamentary Intelligence, (R.) = Review, and (R. and A.R.) = Reports and Analytical Records.*

A Concordance of page numbers and dates of Issue will be found at the end of the Index.

A

Abderhalden, Emil, Handbuch der Biologischen Arbeitsmethoden (R.), 1345
Abdomen, penetrating wound of (J. B. Hance), 331
Aberdovey, 802
Abnormal external jugular vein (A. J. E. Cave), 15
Abortion, Argentine legislation regarding, 162 ; infective, in cattle, and its relation to Mediterranean fever, discussion on, 606
Abrams system in the Law Courts of N.Z. (M.L.), 1136
Accident beds in London (A.), 32
Accidents, hospitals and (A.), 879 ; industrial, in 1924 (P.I.), 471
Acetylene, ethylene, propylene (Francis E. Shipway), 1126
Acidic value of urine in skin and other manifestations (F. Carminow Doble), 272 ; (C.), 361, 407, 464, 465, 516, 517, 568, 629
Acne vulgaris, treatment of (H. G. Adamson) (M.T.T.), 401
Adams, Wilmot, Stricture of anal canal following improper treatment, 490
Adamson, H. G., Treatment of acne vulgaris (M.T.T.), 401 ; Treatment of chronic eczema (M.T.T.), 350
Adder, Life-story of the (Norman Morrison) (R.), 665

SOCIETIES, MEDICAL.

Aberdeen Medico-Chirurgical Society.—Aneurysm, arterio-venous, in the thorax, 441—Encephalitis lethargica, 389—Exhibition of cases, 549—Hæmorrhage, neonatal, 1083
American Heart Association, annual meeting, 522
Brighton and Sussex Medico-Chirurgical Society.—Abdominal emergencies in children, 1080—Bladder, case of epithelioma of, 769—Bronchoscopy and Œsophagoscopy, possibilities of, 78—Cystoscopy, 768—Dyspepsias, painful, and their diagnosis, 548—Exhibition of cases and specimens, 78—Tonsils and adenoids, eradication of, 78
Bristol Medico-Chirurgical Society.—Catarrhal child, discussion on the, 662—Dyspepsias, diagnosis of the, discussion on, 926—Election of honorary member, 663—Exhibition of cases, 663—Fibrocystic disease of humerus, 1131—Nasal sinus disease, diagnosis of, 927—Nervous system, central, surgery of tumours of, 388
British Orthopædic Association.—Essay, award of, 522
Cardiff Medical Society.—Hospital accommodation, provision of, discussion on, 1344
Chelsea Clinical Society.—Annual general meeting, 1325—Climacteric, diseases of, in both sexes, discussion on, 439—Exhibition of cases, 283—Meeting, 573, 691
Edinburgh Medico-Chirurgical Society.—Broncho-pneumonia, fibrosis of bronchi and lungs in childhood following, 1082—Clinical cases, exhibition of, 390, 1183—Dura mater, endothelioma of, 1083—Erythrœdema, 1081—Gonorrhœa in the male, 390—Neurocytoma, case of, 608—Parkinsonian syndrome, so-called, and epidemic encephalitis, 608—Syphilis of central nervous system, treatment of, by tryparsamide, 1298
Edinburgh Obstetrical Society.—84th session of, 786
Fellowship of Medicine and Post-Graduate Medical Association.—Discussion on post-graduate study, 415, 467, 573, 681, 741, 841—Lectures and courses, 105, 210, 260, 313, 363, 467, 499, 573, 690, 797, 901, 951, 1003, 1061, 1109, 1164, 1224, 1276, 1324, 1374
Glasgow Post-Graduate Medical Association.—Teaching arrangements at, 1164
Glasgow Royal Medico-Chirurgical Society.—Malignant diseases of throat and mouth treated by deep X ray therapy, 339—Pulmonary tuberculosis, diagnosis and prognosis of, 927—Tetany, 338
Harveian Society of London.—Annual dinner, 1325—Colon, obstruction of, discussion on, 715
Hunterian Society.—Annual dinner, 260, 415—Annual general meeting, 849—Dinner meeting, 632, 989—Gastric and duodenal ulcers, perforation of, and after, 183—Hunterian oration, 467
International Society of Medical Hydrology.—Annual general meeting, 468, 951
Listerian Society.—Cholelithiasis, some aspects of, 234—Puerperal sepsis in relation to mortality and preventive treatment, 440—"Trial for manslaughter" meeting, 741
Liverpool Medical Institution.—Blood groups, 768—Melanomata, 768—Vesical papilloma, 768
London Association of Medical Women's Federation.—Meeting, 313, 522, 632, 1080—Puerperal morbidity and mortality, prevention of, 493
London Dermatological Society.—Annual general meeting, 1373
Manchester Medical Society.—Digitalis, use and abuse of, 234—Encephalitis lethargica, discussion on, 872—Intrathoracic disease, 1031
Medical Society for the Study of Venereal Diseases.—Arsenobenzol treatment, toxic effects of, discussion on, 925—Clinical cases shown at, 926—Gonococcal and syphilitic diseases of the eye, discussion on, 717—Gonococcal infections, vaccine therapy of, 233—Scientific outlook, value of, to worker in venereal diseases, 233—Venereal diseases in pregnancy, diagnosis and treatment of, discussion on, 1243
Medical Society of London.—Anniversary dinner, 197, 633—Fundus oculi in general medicine, discussion, 547—Lymphadenoma, 337
Medical Women's Federation.—Annual meeting, 1166
Medico-Legal Society.—Meeting, 158—Responsibility, legal, of the surgeon, 899
Medico-Psychological Association.—Annual meeting, 1367—Evidence of before Royal Commission, 1004 1046—Meeting of, 313, 1003
Mental After-Care Association.—Annual meeting, 575
Middlesex Hospital Medical Society.—Annual meeting, 908
National Association for the Prevention of Tuberculosis.—Annual conference, eleventh, 741
National Council for Combating Venereal Diseases.—Proposed change of name, 728, 881
North of England Obstetrical and Gynæcological Society.—Exhibition of cases and specimens, 441—Pelvic adenomyoma, pathology of ectopic Müllerianoma, discussion on, 129, 440—Uterus as a centre of toxins and irritative products, 440
North-Western Tuberculosis Society.—211, 632
Pathological Society of Great Britain and Ireland.—Meeting in Liverpool, 149
Plymouth Medical Society.—Clinical meeting, 664
Romford and District Medical Society.—Annual dinner, 402
Rontgen Society.—Annual meeting, 1225—Meeting, 260, 464, 742
Royal Academy of Medicine in Ireland.—Auricular fibrillation with slow ventricular rate, 610—Dextrocardia, congenital, 609—Infant mortality, 663
Royal Medico-Chirurgical Society of Glasgow.—Arthritis, rheumatoid, 20
Royal Society of Medicine.—Abortion, infective, in cattle and its relation to Mediterranean fever, discussion on, 606—Anæsthetics, local, drugs used in, 437—Bladder and prostate, radiotherapy and electrotherapy in diseases of, discussion on, 281—Blindness, congenital, without obvious ocular or central cause, 129—Clinical cases, 1243—Colon disease, X ray diagnosis of, discussion on, 1079—Coxitis, non-tuberculous, differential diagnosis of, discussion on, 819—Critchett, the late Sir Anderson, 436—Dacryocystitis, operative treatment of, 1343—Dacryocystostomy, intranasal, 1242—Deafness, mumps, bilateral, 975—Deafness, nerve, sudden bilateral, 975—Demonstrations, 1243—Diphtheria, preventive control of, 492—"Electronic reactions," 177—Encephalitis lethargica, mental sequelæ of, discussion on, 181, 280; sinus condition in, 1243—Endocrine therapy, discussion on, 739, 766, 976—Exhibition of cases, 437, 1343—Eyes, diseases of, common to man and animals, discussion on, 1029—Facial nerve anastomosis in facial nerve palsy, 336—Fibrositis, discussion on, 545—Fistulæ, 387—Gastric and duodenal ulcer, 1239—Hearing, artificial aids to, 1297—Hypoglycopyresis, 974—Hemianopia, bi-temporal, from fracture of skull, 129—Intracranial infection by erosion from subperiosteal abscess, 607—Jullundur cataract operation, safety limits of, 1344—Labyrinth, sequestra of, 607—Laryngectomy, speech after, 1241—Laryngitis, tuberculous, tracheotomy in, 1242—Lecture at, 311—Light department for surgical tuberculosis, organisation of, 871—London in the 18th century, health of, 1240—Mastoid emissary vein and its surgical importance, 975—Mastoid operation, radical, performed by Nature, 976—Metabolism and the sympathetic system, 974—Milk-supply, control of tuberculosis and the, discussion on, 334, 491—Mumps deafness, bilateral, 975—Nichols prize awarded to Dr. George Geddes, 573—Nystagmus, miners', ætiology of, discussion on, 436—Optic nerve tumours, 437—Orbit, inflammatory pseudo-tumours of, 128—Pharynx, larynx, and mouth, diseased conditions of, 1241—Plastic surgery of malignant disease of pharynx and larynx, 1240—Pterygo-maxillary abscess, otogenic, 607—Pulmonary affections, post-operative, 333—Radiation, general survey of, 661, 1130—Radiations, tissue response to, 1130—Radiotherapy, high voltage and, 1130—Resignation of secretary, Sir John MacAlister, 883—Rhinorrhœa, paroxysmal, discussion on, 766—Septicæmia and acute middle-ear infections, 336—Septicæmia, treatment of, 688—Social evening, 51, 502, 673, 883, 1144, 1224—Tuberculosis, control of, and the milk-supply, discussion on, 334, 491—Tuberculosis in the Services, discussion on, 821—Ultra-violet light, susceptibility of nocturnal animals to, 127—Urinary tract, bacterial infections of, discussion on, 923—Vitamin deficiency, non-specific disturbances of health due to, discussion on, 385, 573, 659—X ray treatment of carcinoma of breast, 660
St. Mary's Hospital Institute of Pathology and Research.—Filterable viruses, 1183
St. Mary's Medical Women's Association.—Formation of, 158
Society for Constructive Birth Control and Racial Progress.—Special meeting, 522
Society of Medical Officers of Health.—Dick reaction and serum treatment of scarlet fever, discussion on, 1294—Maternity and child welfare group, meeting of, 415
Society for the Study of Inebriety. Annual meeting, 522—Meeting, 1373
Society of Superintendents of Tuberculosis Institutions.—Meeting, 633
Tuberculosis Society.—Annual meeting and dinner, 1373—Meeting, 105, 633—Provincial meeting at Cambridge, 789
Tuberculosis Society of Scotland.—Meeting, 1374
Ulster Medical Society.—Epidemic encephalitis in Belfast in 1924, 390
West Kent Medico-Chirurgical Society.—Exhibition of cases and specimens, 235—Meeting, 105, 336, 574, 849

RESISTANCE TO DISEASE

A New Orientation.
BY
HARRY MERRALL, M.B., and Ch.B.

THE greatest authorities throughout the world teach us that virtually the only natural defence against the micro-organisms which directly or indirectly occasion nearly every disease to which human flesh is heir, is that provided by the blood. Yet the immense majority of these diseases and disabilities are due to microbes with which that fluid never comes into contact.

The author expounds a new theory as to wherein the sure defences lie.

Goulstonian Lectures

ON THE STUDY OF

GASTRIC FUNCTION IN HEALTH AND DISEASE.

By JOHN A. RYLE, M.D., F.R.C.P. Lond.,
ASSISTANT PHYSICIAN AND LECTURER ON MEDICAL PATHOLOGY, GUY'S HOSPITAL.

LECTURE III.*

Part I.

One of the foundations of clear thinking in the natural sciences is classification. With symptomatology, or the science of the evidences of disease, it should not be otherwise; and yet, if we set aside the unsatisfactory division into "organic" and "functional," we find that the classification of the dyspepsias has remained to this day in a curious state of confusion. It has been one of the objects of my discussion to show that all gastric symptoms express only a derangement of function, for they may occur equally in the absence or presence of local organic disease and are shown to be due to disorders of tonus, peristalsis, and motility. The very word "dyspepsia" signifies disturbed function, but at an earlier date it was exclusively used to describe disturbances occurring independently of organic disease. Thus, Brinton,[1] in 1858, although he clearly foresaw that it must undergo further subdivisions, held that the term implies "not only that a certain amount of digestion is (though with difficulty) effected, but that this difficulty is not due to any serious structural lesion. To call by the name of 'dyspepsia' such an impairment of function as we find associated with cancerous or ulcerous destruction of the gastric tissues, would," he remarks, "obviously be almost as absurd as to call strangulation 'dyspnœa,' or to speak of a beheaded criminal as having been rendered 'insensible.'" In 1884 we find the late Sir Clifford Allbutt,[2] in his Goulstonian lectures, attaching a wider interpretation to the term and appealing for its proper recognition as implying not a disease but a symptom; in his own phrase, "it names not the causes nor the processes of the evil, but its consequences." Gradually there has followed a more general acceptance of this usage; I think most desirably so, for its employment in the original sense has been and still remains very harmful to medical practice. Even now dyspepsia is constantly employed as a diagnostic label, and while no physician would be content to enter a case in his index as a case of "dyspnœa" or "insensibility," "dyspepsia" and "indigestion" are apparently very frequent entries. The man of judgment, it is true, reserves the term for those cases in which he is persuaded of the triviality of the condition or in which there is a cause to be found in some corrigible error of diet or habit. There are others, however, who, whether from faulty tradition or training, obscure their own vision and postpone accurate diagnosis by a too ready substitution of the symptom for the disease. We must all be familiar with cases of ulcer, cancer, appendicitis, cholecystitis, pulmonary tuberculosis, alcoholism, tabes dorsalis, oral sepsis, or psycho-neurosis, in which dyspepsia has too long been regarded as a sufficient diagnosis either by the patient himself or by his medical attendant. And we must all have experience of cases of our own in which the surgeon or subsequent clinical developments have revealed the true cause of unexplained or ill-explained dyspeptic symptoms. Quite recently I was consulted by a man with a long and characteristic story of duodenal ulcer developing into an established stenosis with the symptoms and physical signs typical of that condition. He had been told by six medical men that he had "dyspepsia." A large proportion of all patients who are ultimately shown to have gastric or duodenal ulceration have had to remain content with a diagnosis of "dyspepsia" for months or years, and as the success of medical treatment in these cases and the avoidance of operation depend largely upon an early diagnosis, delay of this kind is, to say the least, unfortunate.

There is, therefore, good reason to plead for the employment of "dyspepsia" in its only permissible sense as indicating a group of symptoms for which a proper cause or causes must invariably be sought, and to urge that any future classification of the dyspepsias must be based on ætiological considerations. In the past attempts have been made to classify on a basis of main symptoms, and to this doubtful plan we owe the origin of such terms as "flatulent dyspepsia" and "acid dyspepsia"—excusable when they were coined but not to be accepted now. In descriptions such as "fermentative" and "atonic" dyspepsia we have witnessed an attempt to classify on the basis of a hypothetical pathology, which can now be superseded, for we have come to recognise that gastric fermentation is rare and that it is exceptional for it to occur apart from pyloric stenosis or obstruction; that hypotonus (for which the term "atony" is sometimes loosely substituted) is usually an expression of general ill-health; and that the nearest approach to genuine atony is the extreme grade of dilatation which only accompanies the later stages of obstructive pyloric or duodenal lesions. Even in the most recent editions of the well-known text-books of medicine there is a complete lack of uniformity and ordered teaching, and terms such as atonic dyspepsia and gastralgia abound. The most accepted plan would seem to be the very artificial classification into sensory, motor, and secretory neuroses, but it is difficult to see how the student can extract from these descriptions any clear conception to guide him in his practice. The division into medical and surgical dyspepsias can meet with no approval. "Surgical dyspepsia" is held to designate a type in which surgery may give or help to give relief, but it might equally well imply a dyspepsia which results from surgical intervention. In no class of case is it more desirable to avoid the cleavage between medicine and surgery which has been the tendency of recent years; in no class of case is close coöperation of medical and surgical opinion more fruitful in results.

If we accept, as a working basis, the conclusions arrived at in my previous lectures, it would seem reasonable to advocate the arrangement about to be described, which recognises at once the importance (1) of assigning to every case and type of dyspepsia a definite basic cause or group of causes; (2) of tracing the gradations between healthy and morbid states; and (3) of regarding all dyspeptic symptoms as expressions of disturbed reflexes. I am aware that this classification is an elementary one and that, consciously or unconsciously, a similar or identical classification must now be widely employed by others, but there cannot, I believe, be any harm in setting it clearly forth. At the least it may serve to emphasise the need for system in the place of present chaos, and to indicate that no such "disease" as "dyspepsia" exists.

Craven Moore[3] has outlined a not very dissimilar classification, and to him, although he gives it a somewhat different application, we owe the term "reflex dyspepsia," which I have previously employed in describing the dyspepsias falling into my fourth group.

Classification of the Dyspepsias.

Group 1. *Habit Dyspepsias.*—Dyspepsias resulting from faulty physical habits. Examples: over-eating, under-eating, over-work, lack of occupation and exercise; insufficient mastication; constipation, or some combination of these factors.

Group 2. *Nervous or Psychogenic Dyspepsias.*—Dyspepsias due to faulty mental or nervous adjustment. Examples: nervous tricks such as aerophagy, nervous exhaustion,

---

* Lectures I. and II. appeared in The Lancet of March 21st and 28th respectively.

585756

worry and anxiety states, hysteria, hypochondriasis, and refusal of food.

Group 3. *Toxic and Infective Dyspepsias.*—Dyspepsias due to (*a*) tissue poisons, and (*b*) general and local infective disease, and other and more obscure conditions interfering with general health and nutrition. Examples: (*a*) alcohol and tobacco; (*b*) pulmonary tuberculosis; oral sepsis; severe anæmias; states of general debility associated with auto-intoxication, muscular hypotonus, loss of fatty deposits, and visceroptosis.

Group 4. *Irritative Dyspepsias.*—Dyspepsias due to stimuli originating in a local or distal organic lesion. Examples: gastric and duodenal ulcer; gastro-jejunal ulcer; chronic infections of the appendix and gall-bladder; special sense disturbances such as astigmatism; and central nervous lesions such as tabes dorsalis.

Group 5. *Mechanical Dyspepsias.*—Dyspepsias due to gross structural disease or to surgical modifications of the anatomy of the stomach. Examples: pyloric stenosis; hour-glass stomach; chronic extensive ulceration; certain complications and sequelæ of gastric surgery; and carcinoma ventriculi.

It should hardly be necessary to point out that there is a frequent over-lapping of these groups. The causal factors cited in Group 1, habit dyspepsias, are not uncommonly associated with those cited in Group 2, nervous dyspepsias. A symptom such as vomiting originally due to a physical cause such as pregnancy may be perpetuated and aggravated in an apprehensive or hysterical subject and develop, as Hurst[4] has shown, into the so-called "pernicious vomiting" of pregnancy. Gastric ulcer and pulmonary tuberculosis may coexist. Mental worry and fatigue frequently aggravate the symptoms due to organic diseases such as duodenal ulcer. Two foci of irritation such as cholecystitis and appendicitis may be present in combination. Chronic duodenal ileus in association with emotional instability may produce dyspeptic symptoms which neither factor alone would have been capable of producing.

Every case of dyspepsia is indeed a general medical problem. In no other group of disorders are the balance and the perspicacity of the physician more severely tried, and in no other group is greater judgment required for assessing causal and contributory factors and for the interpretation of special findings.

A few years ago I was anxious to ascertain the distribution in practice of these five groups of dyspepsia. In a series of 267 unselected cases, for the most part carefully investigated, the percentages were found to be distributed as shown in Table VI. It should be mentioned that at that time I included alcoholic dyspepsia in Group 1 instead of Group 3, but the percentages would not be appreciably modified by the necessary interchange. Groups 4 and 5 I have here combined, as at that time I included ulcer in Group 5, and redistribution would now be difficult. The larger proportion of these cases, having resisted treatment, had been referred for a fuller investigation, so that it must be assumed that Groups 4 and 5 contain a much larger percentage of cases than they would do in the total population of dyspeptics. The figures probably represent, roughly, the proportions encountered in consulting or hospital practice, and indicate that even in this class of work about 50 per cent. of dyspepsias are due to extra-gastric causes of a general kind; of the remaining 50 per cent. from one-third to one-half are due to local lesions remote from the stomach. Craven Moore[3] suggested the term "reflex dyspepsia" for hyperchlorhydria, intending to imply the existence of an irritative lesion or of increased excitability of the nervous mechanism, or both, but since I shall endeavour to show that all subjective dyspeptic symptoms must depend on disturbed reflexes the term becomes unsuitable for purposes of the present classification. "Sympathetic dyspepsia" is also open to criticism, although perhaps it indicates more clearly the idea of sympathy between one viscus and another or between the stomach and distant parts of the body. For these reasons, and lacking a better appellation, I have employed the term "irritative dyspepsia" to describe those cases in which nervous stimulation or inhibition can be traced to a local focus of irritation.

Table VI.

Group.	Per cent.
1. Habit dyspepsias	12
2. Nervous dyspepsias	24
3. Toxic and infective dyspepsias	12
4 and 5 (combined). Irritative and mechanical dyspepsias	52

In the case of a viscus like the stomach, whose nervous mechanisms are so complex and so incompletely understood, it is almost impossible to determine with precision the nature of the neural element in each of its disorders. The points at which an interference with the reflex arc may occur are numerous and the nature of the interference is often hypothetical. Observations which apply to the cerebro-spinal system do not necessarily apply to the autonomic nervous system. Nevertheless, a reference to the mechanisms influencing a simple cerebro-spinal reflex may help to simplify the conception of the reflex origin of dyspeptic symptoms. In the case of a tendon reflex we recognise that the response may be influenced (1) by a central or peripheral nerve lesion; (2) by varying the type or force of the peripheral stimulus; (3) by mental concentration or distraction, or by inborn or acquired temperamental qualities; (4) by physiological shortening, or lengthening, or by fatigue, intoxication, or disease of the muscle-fibre itself.

In the case of the stomach, too, the responses may be influenced (1) by central nervous causes, as in the vomiting of cerebral tumours and the pain and vomiting of tabetic crises; (2) by increased peripheral stimuli, as in gastric and duodenal ulcer, chronic appendicitis, or cholecystitis; (3) by mental or emotional causes influencing the conductivity or the threshold to stimulation of the sympathetic or para-sympathetic; (4) by the physiological characters, fatigue, intoxication, or disease of the gastric muscle-fibre itself. Both "pressor" effects, producing exaggerated muscular action, as in the irritative dyspepsias, and "depressor" effects, producing relaxation or inhibition, as in the dyspepsias due to fatigue and intoxication, are encountered.

If we now re-examine the five groups of dyspepsia in the light of these rather elementary considerations we find that in Group 1 (Habit Dyspepsias) the symptoms may be traced to the fact that the work demanded of the muscle-fibre is out of proportion to the requirements of the body at the time. In other words, there is fatigue, through overloading or over-activity, of the muscle-fibre. By diminishing the work of the stomach or increasing the requirements of the body on the one hand, or by more food and physical relaxation on the other, we rest or refresh the muscle and relieve the dyspepsia.

In Group 2 (Nervous or Psychogenic Dyspepsias) nervous conductivity has been depressed or enhanced on the afferent or efferent side by mental or emotional processes or by nervous fatigue; motor excitation and sensibility may both be increased, and not uncommonly fear of organic disease aggravates the condition and a vicious circle is established.

In Group 3 (Toxic and Infective Dyspepsias) muscular function (and possibly nervous function also) is deranged by the circulating toxins. In the toxic dyspepsias local influences, and in the infective dyspepsias general influences predominate. In tobacco dyspepsia sympathetic inhibition allows exaggerated vagal action so that a "pressor" effect is obtained, but in all the other toxic and infective dyspepsias "depressor" influences predominate.

In Group 4 (Irritative Dyspepsias) the peripheral stimuli are exaggerated by local disease of a mechanical or inflammatory kind, and excepting in the case of the special sense disturbances the effects are always of the "pressor" variety.

In Group 5 (Mechanical Dyspepsias) the symptoms are due to destruction of the continuity of the muscle-fibre, or to modification of the mechanisms which control emptying.

We are now in a position to discuss more intimately the nature of the main symptoms in the individual varieties of dyspepsia composing these several groups. For illustrations I have referred principally to my own case-notes and test-meal findings. For the notes of a few of his cases in the investigation of which it was my privilege to coöperate, I am indebted to Dr. A. F. Hurst.

1. Habit Dyspepsias.

In a small series of cases classified as belonging to this group it is noteworthy that all happened to be men. Of these more than half were between the ages of 27 and 35 and had seen war service. Throughout their service they had been entirely free from dyspeptic symptoms, notwithstanding that some of them had had symptoms before the war. They had returned to sedentary occupations, generally office life. In the remaining cases the patients were older or younger, but were invariably leading unhealthy and inactive or irregular and restless lives. The chief complaints were of discomfort and fullness in the epigastrium developing soon after food, flatulence, and a poor morning appetite, or a capricious appetite. In a few instances, however, the discomfort developed at a long interval after food and was eased by food. A clear definition and localisation of the discomfort were almost constantly lacking and physical examination revealed nothing abnormal. In cases in which anxiety and the fret of civilised toil are added to an unsuitable life discomfort may occasionally give place to real pain simulating that of organic disease. When I have had an opportunity of investigating cases of habit dyspepsia more closely I have found no consistent objective evidence of motor or secretory abnormality. In other words, derangement of function is usually too slight to be susceptible of demonstration by the ordinary physical or chemical methods, although its nature may be readily and reasonably surmised on clinical grounds. The nature of the response and the time of arrival of the discomfort are determined partly by the particular irregularity in the patient's mode of living, but partly also by the physiological characters or habitus of his stomach. Thus the man who takes normal or bulky meals at too frequent or normal intervals, or is of the hyposthenic type, experiences discomfort shortly after meals; while the man who goes too long without meals, or is of the hypersthenic or mentally overactive type, will be more liable to experience discomfort before meals. Treatment is seldom difficult if the patient can be persuaded of the origin of his symptoms. Regularisation of habits, readjustment of meal-times, a reduction in the quantity, particularly of bulky carbohydrate food, with increased exercise, on the one hand, or more frequent meals and relaxation, on the other, quickly bring improvement.

2. Nervous or Psychogenic Dyspepsias.

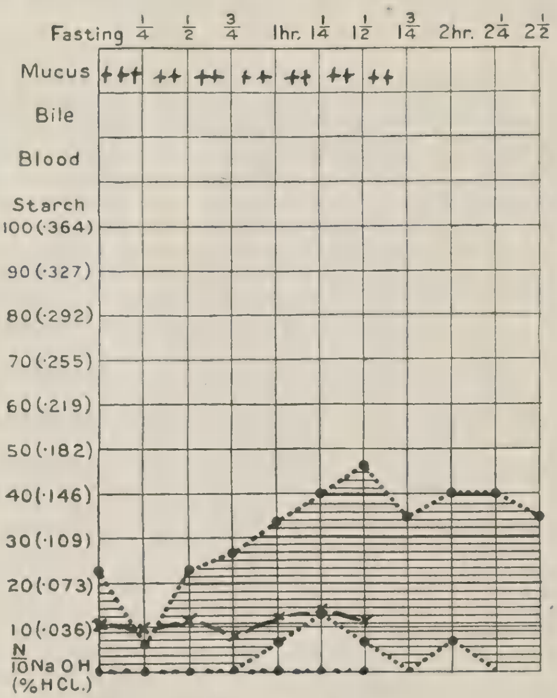
Of my cases indexed under this heading men and women provided an equal proportion. Almost without exception they complained of flatulence as a leading symptom and in many I noted active air-swallowing movements during the physical examination. Epigastric discomforts, and more rarely pain, were complained of, but the relationship of symptoms to food was less definite than in the other groups. Worry, fear, anxiety, and noises were the principal aggravating factors. Nausea and capricious appetite and heartburn were also mentioned, and this is the only group in which I have personally encountered the symptom bulimia. Fastidiousness in the selection of food and exclusion from the dietary of one article after another for its supposedly noxious qualities help to complete a familiar syndrome. There is a common association of other visceral symptoms such as palpitations or frequency of micturition and, in women particularly, of vaso-motor disturbances. Before investigating the group I had scarcely expected to find that flatulence was such a constant feature. It is presumably induced in some cases by one of the physical causes already mentioned, but I believe that anxiety alone may initiate the swallowing movements necessary for the production of the symptom. Radiographic and chemical tests reveal no constant departure from the normal. Such investigations should only be undertaken to exclude organic disease or for the specific purpose of relieving a phobia or providing stronger reassurance. Although, as I have stated, the discomforts seldom show an accurate relationship to food, I think they are more liable to develop at those times at which normal gastric sensations are evoked—that is to say, when the stomach is empty or recently filled. Furthermore, the nature of the response, as in other groups, is in part determined by the physiological type or gastric habitus of the individual.

3. (*a*) Toxic Dyspepsias.

(i.) The symptoms of *alcoholic gastritis* are too familiar to require detailed description. They include nausea, retching, and vomiting due to irritation of the mucosa and excessive secretion of mucus, and all showing a particular liability to occur in the morning before breakfast; loss of breakfast appetite, due to impaired tonus; and morning and post-prandial diarrhœa due to the achlorhydria. The vomited material consists largely of mucus, and Hurst[5] has pointed out that much of this is derived from the œsophagus. It is often frothy and is consistently referred to by the patient as "phlegm." If pain is complained of it has rather a diffuse and burning character. The same syndrome, but generally in less pronounced form and without the other physical and psychological stigmata of alcoholism, occurs in gastritis due to excessive tea-drinking or gross oral sepsis. Beaumont's experiments on Alexis St. Martin and clinical experience with the gastric tube show that it is also possible for gastritis to occur without any local subjective symptoms. As has been previously suggested, the anorexia of gastritis is probably related to the general toxæmia and perverted metabolism of alcoholism, for in the earlier stages appetite returns with great rapidity when abstinence is insisted upon and almost before the mucosa could be expected to have become normal. Nevertheless the coating of mucus must inhibit those appetite sensations which depend on the ingestion of food, just as it inhibits the reflex secretion of gastric juice which normally results from contact of soluble food with the mucosa. The radiographic findings are variable and of no diagnostic importance. Hyperchlorhydria and achlorhydria both appear more frequently than in health, but achlorhydria is more common in established cases and increasingly so with the duration of the alcoholic habit—it is thus generally present in cirrhosis of the liver. The frequent association of achlorhydria with gastritis has been recognised since the introduction of the one-hour test-meal, but this method cannot detect delayed or transient rises in acidity. Bell,[6] in 11 cases of chronic gastritis examined with the fractional method, reported complete achlorhydria in five cases, hypochlorhydria and low normal curves in three cases, and hyperchlorhydria in three cases. Barber and Ryle,[7] examining 12 cases of acne rosacea, the occurrence of which apart from true gastritis—whether due to alcoholism, tea, or oral sepsis, or to a combination of these causes—is doubtful, found that seven cases showed complete achlorhydria, while of the remaining five one showed no secretion of free acid until after one hour and two showed a temporary high peak of acidity with an abrupt fall to the base line. The resting secretion in cases of gastritis with achlorhydria is small in amount and extremely viscid, consisting almost entirely of mucus. It sometimes has a peculiar rancid odour and microscopically may show an excess of pus cells. Before accepting the pus as of gastric origin it is important, as Ganz[8] has shown, to compare the cell content of the spittle and the fasting-juice. Mucus is generally present in excess throughout the test. That the achlorhydria is not a permanent condition is shown by Charts 13 A and 13 B, which were obtained in a case of alcoholic gastritis, one before, and the other after lavage. A similar improvement may result from abstinence combined with other rational treatment.

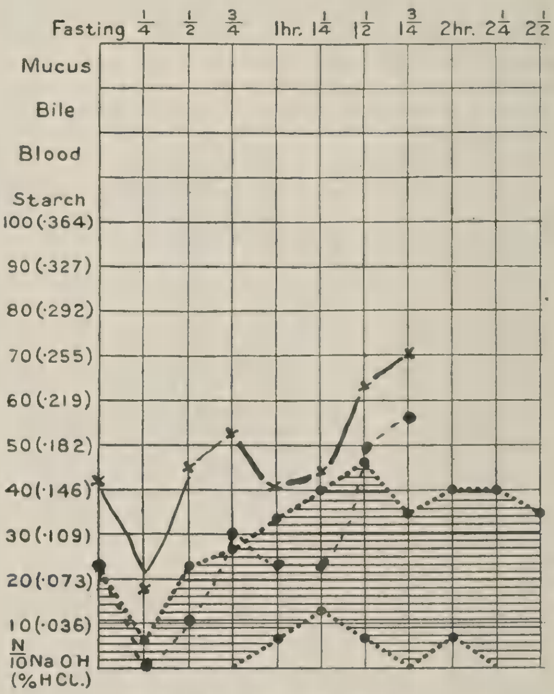
(ii.) *Tobacco Dyspepsia.*—Nicotine was shown by Langley[9] to paralyse the synapses of the sympathetic nervous system, so that we might anticipate dyspeptic symptoms from unopposed vagal action in habitual smokers. Although, however, we often prescribe a curtailment of tobacco in dyspeptic cases, and particularly in cases of duodenal ulcer, and although patients with duodenal ulcer not infrequently observe for themselves that smoking aggravates their symptoms, genuine tobacco dyspepsia is a rare condition. I have seen one case of a man with typical hunger pains and relief by food who was an excessive smoker of strong tobacco, and who had clearly recognised that he could invariably and completely relieve his symptoms by not smoking. In fact, his only object in seeking medical advice was to obtain a remedy which would enable him to go on smoking. It is, of course, conceivable that he may have had a duodenal ulcer or some other irritative lesion which required the additional influence of nicotine to waken the painful sensations. Unfortunately he did not give me the opportunity of investigating his case completely, but I have seen no other case of duodenal ulcer in which the symptoms could be wholly relieved by the simple cessation of smoking.

CHART 13 A.



Alcoholic gastritis.

CHART 13 B.



Same case as 13 A after lavage.

3. (*b*) DYSPEPSIA OF INFECTIVE ORIGIN.

(i.) *Dyspepsia due to Tuberculosis.*—The dyspepsia of pulmonary tuberculosis occurs in two distinct types or stages of the disease. It accompanies the active stage, when anorexia, pain after food, nausea, and vomiting are the principal complaints, and the symptoms of gastric ulcer may sometimes be very closely simulated. At this stage pulmonary and general symptoms predominate and diagnosis is seldom long in doubt. Secondary dyspeptic symptoms are also common in those chronic states of impaired health due to a pulmonary lesion which is presumed, on clinical grounds, to be healed; or in which pulmonary symptoms are lacking or inconspicuous or attributed to hilum tuberculosis; or in which the existence of lung disease has never previously been suspected at all. In such cases the symptoms are an exaggeration of the ordinary symptoms of a hyposthenic or fatigue dyspepsia. They include poor appetite and a fullness or discomfort developing soon after food, which is particularly troublesome at the end of the day when fatigue is greatest. The symptoms are relieved by rest. In either group appropriate treatment of the general condition, if it be followed by a favourable response in other respects, brings a return of appetite and improvement in the gastric symptoms. The radiographic and test-meal findings are variable, but hypotonus and hypoacidity predominate. Radiograms of the chest are more likely to be helpful in confirming a clinical suspicion of the cause of the dyspepsia than radiograms of the stomach. Leb[10] X rayed the chest in all patients he saw with dyspepsia associated with an "atonic" (hypotonic) stomach and found evidence of active or healed tuberculosis of the lungs in a large number.

(ii.) In *Visceroptosis* the dyspepsia is again of the fatigue or hyposthenic variety with feelings of discomfort and more rarely pain developing soon after food, poor appetite, and sometimes nausea and heartburn. Generally there is aggravation by the erect posture, and relief by recumbency. With extreme degrees of gastroptosis there is delay in emptying and with the test-meal either achlorhydria or a very low but slowly climbing type of acid curve is shown. X ray examination reveals an elongated "J"-shaped type of stomach with poor tonus and motility, the greater curvature low in the pelvis, and a constriction in the long vertical limb resulting from traction exerted by the weight of the barium. Of the cases of visceroptosis with undernutrition a considerable proportion would seem to be due to dormant pulmonary tuberculosis aggravated by domestic fatigue.

(iii.) *Anæmic Dyspepsias.*—The dyspepsias accompanying anæmia also simulate the fatigue type of dyspepsia and, as with the cardiac symptoms of anæmia, are probably due to muscle exhaustion from deficient oxygenation. In chlorosis and secondary anæmias, heart-burn and nausea are special symptoms which seem to occur with more than accidental frequency. Acidity is generally low, and complete achlorhydria is not uncommon. In Addison's anæmia complete achylia is an essential part of the disease and not secondary to the anæmia; in fact, it precedes its development and persists even after the hæmoglobin and red cells have returned to a normal figure. The rate of emptying in most cases of achylia is rapid, and a painless morning or post-prandial diarrhœa is common. I have once or twice met with a complaint of hunger discomfort in association with achylia, due presumably to the rapid emptying.

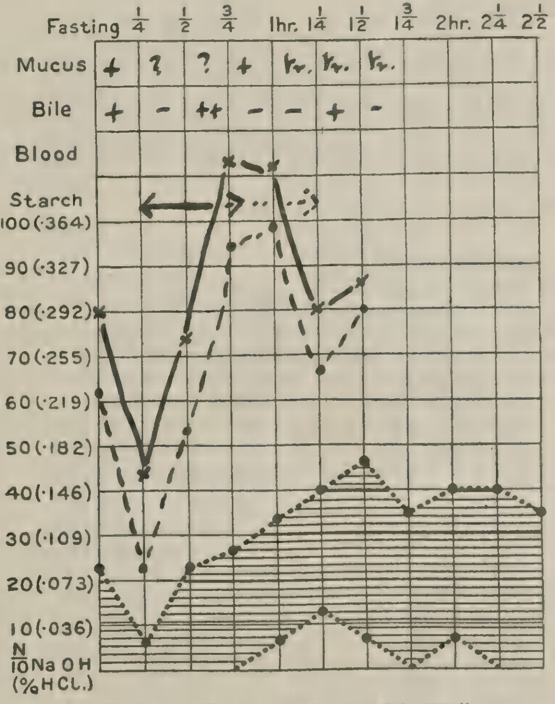
4. IRRITATIVE DYSPEPSIAS.

The painful dyspepsias due to reflex stimulation from an ulcer or inflammation of the gall-bladder or appendix have already been discussed at some length, and I shall here only draw attention to certain special features pertaining to each example. It should again be explained that the secondary gastric symptoms alone are under review and not the symptoms directly attributable to the local lesion.

Duodenal ulcer, from its close proximity to the pylorus and its constant situation, is the most true to type. The character of the pain is gnawing or aching or sometimes referred to as a feeling of great pressure in the epigastrium. Its localisation is in mid-epigastrium or to the right of this point. It is confined to an area which can usually be covered by the tips of two or three fingers, but it may be diffused about the epigastrium and sometimes rises into the chest. It commonly appears between two and four hours after the last meal, but the interval of time is determined by the size of the meal and the motility of the individual stomach. It varies greatly in its severity, but is only very occasionally completely incapacitating or agonising. Langdon Brown[11] has recorded excessively severe pain in the case of ulcers adherent to the pancreas; I have several times confirmed this observation, and the only cases of duodenal ulcer in my experience in which it has been necessary to give morphia for relief of the pain were complicated in this way. The pain lasts for varying periods up to and beyond one hour, in fact until the stomach is replenished or completely empty or until relief follows vomiting or the administration of drugs. The night pain shows the longest duration and may last for many hours because it is not automatically relieved by a meal. The pain is initiated and aggravated by hunger, or rather by readiness for food, by fatigue, cold, worry, and sometimes by smoking. It is relieved by food, rest, warmth, and peace of mind; by alkalies, and by belladonna and atropine. Appetite is usually good. The radiographic signs—namely, exaggerated tonus and peristalsis, and sometimes rapid evacuation of the meal—need not again be discussed, but test-meal findings show certain characters which deserve closer consideration than I have previously given to them. The fasting juice in a considerable proportion of cases is increased in amount up to 80 or 100 c.cm. or more; it is perfectly clear, limpid, and highly acid and contains little or no mucus. After the initial fall in acidity due to withdrawal of the fasting specimen and dilution with the gruel, there is a steady rise to a high point, followed either by a steep drop with excessively rapid emptying as in Chart 14, or a sustained plateau with rapid or normal emptying and continuous after secretion as in Charts 15 and 16. In these cases there is evidence of a hypersecretion and continued secretion which are seldom found in other dyspepsias. In my own experience, hyperchlorhydria with the additional findings now mentioned is almost pathognomonic of duodenal ulcer. According to the combined figures of Bell[6] and Hunter[12] hyperchlorhydria is present in 70 per cent. and normal acidity in 30 per cent. of cases of chronic duodenal ulcer, while hypochlorhydria and achlorhydria are not recorded. As will be shown later, the test-meal findings in duodenal ulcer, in addition to being of contributory diagnostic value, may also give help in determining the suitability or otherwise of individual cases for the operation of gastro-jejunostomy.

Gastric ulcers show a wider range of variability in position and their symptoms are consequently less defined. In so-called "typical" cases or in those with a story of hæmateme is a diagnosis may sometimes be made on the anamnesis alone, but it will be agreed that the history is often misleading. For instance, there may be vomiting without pain; flatulence or discomfort may be the only symptoms mentioned; and the time relationships to food of pain or discomfort are inconstant. The pain is greater with the deeper ulcers; it has the same character as the pain of duodenal ulcer in so far as it is described as gnawing or aching; it is felt in mid-epigastrium, or to the left of this point; it is confined to an area which can be covered by the tips of two or three fingers, but may be much more widely diffused. Excepting in old-standing cases with extensive ulceration and physical exhaustion or secondary anæmia, or in the presence of organic hour-glass contractions, it is seldom agonising or wholly incapacitating. It lasts for varying periods; is initiated by food, and more by solids than by fluids; and is more troublesome with protein foods requiring prolonged gastric digestion. It is relieved by rest, starvation, and vomiting. Appetite is not good and the patient "is afraid to eat." Partly by reason of its higher incidence in women hypotonus is more common than hypertonus. The most important radiographic sign of perverted muscular function (and this is by no means constant) is the incisura or spasmodic hour-glass constriction. When the ulcer is situated close to the pylorus and the stomach is hypertonic the symptoms of duodenal ulcer are reproduced and hyperchlorhydric curves are obtained. Otherwise the fractional test-meal is of small diagnostic value, for every variety of curve may be given from achlorhydria to hyperchlorhydria, and normal curves predominate. In the combined series of Bell[6] and Hunter[12] the figures for gastric ulcer were as follows: normal acidity, 57 per cent.; hyperchlorhydria, 33 per cent.; achlorhydria, 10 per

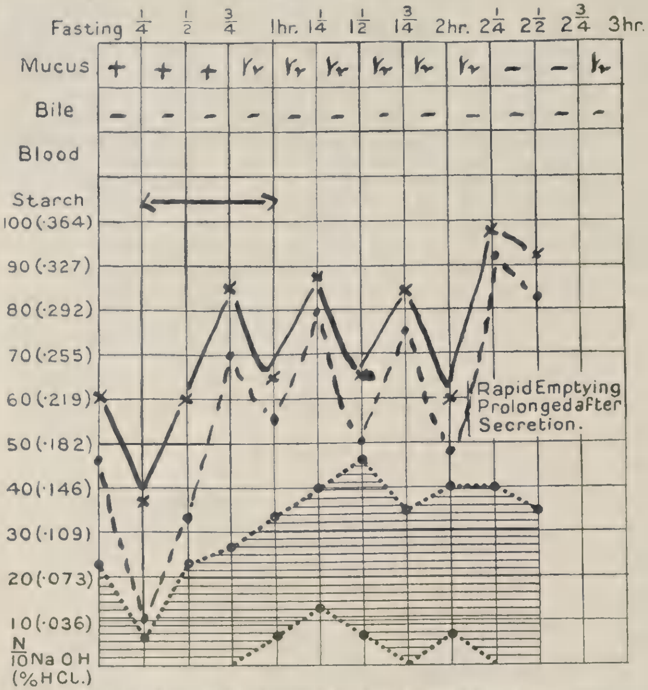
CHART 14.



Duodenal ulcer with extreme "hurry."

cent. In its objective signs, therefore, as well as in its symptoms, gastric ulcer is shown to exhibit a far less constant behaviour than duodenal ulcer. This irregularity can be related to its lack of close association with the pylorus.

CHART 15.



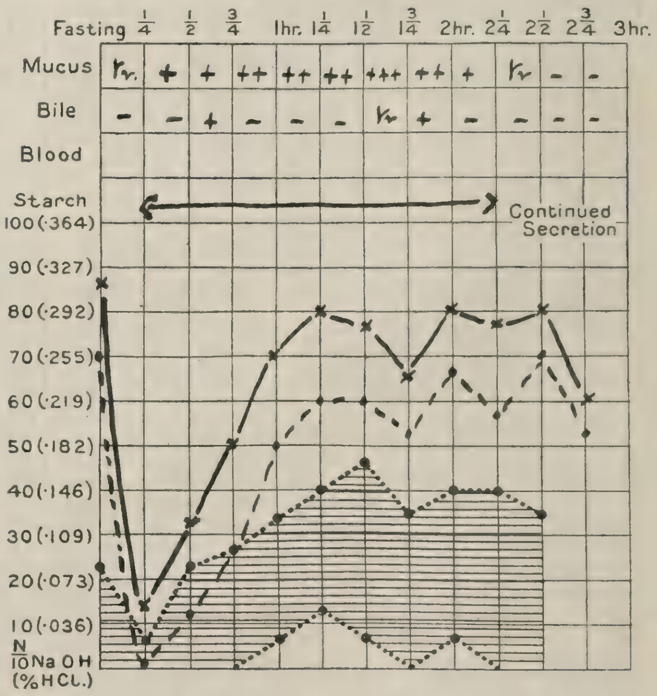
Duodenal ulcer with "hurry" and continued hypersecretion.

Jejunal and gastro-jejunal ulceration is usually a complication of the operation of gastro-jejunostomy performed for an active duodenal ulcer. The symptoms simulate those of duodenal ulcer—another observation suggesting that the type of dyspeptic response depends rather upon the physiological habitus of the stomach than upon the site of the lesion. The pain is more difficult to relieve with medical treatment and the ulcer is more intractable than is the case with the primary ulcer. X ray examination reveals no constant disturbance of function apart from that due to the gastro-jejunostomy. The fractional test-meal gives hyperchlorhydric curves, the acidity often reaching a higher point than before the operation.

Cholecystitis, and gall-stones with cholecystitis may or may not produce a secondary dyspepsia in addition to the local symptoms. In association with a hypertonic stomach the symptoms of duodenal ulcer may be very closely simulated; appearances suggesting pyloric spasm are seen with the X rays, and climbing hyperchlorhydric curves are obtained. Indeed, the differential diagnosis between gall-bladder disease and duodenal ulcer, as has been repeatedly observed, may be one of the most difficult in medicine, especially as both lesions give rise to tenderness and reflex signs in the right upper quadrant of the abdomen. Flatulence and epigastric distension are frequent complaints in these cases, and in well-nourished patients over 40 complaining of attacks of a "windy" dyspepsia which necessitates the loosening of clothes or corsets, the possibility of gall-bladder disease is always to be entertained. With a hypotonic stomach the symptoms of gastric ulcer are closely simulated and the test-meal shows hypochlorhydria or achlorhydria. In the chronic mild forms of cholecystitis without cholelithiasis, due to infection with *Bacillus coli* and occurring for the most part in sallow and poorly nourished women, nausea—according to my records—is described with greater frequency than in any other type of dyspepsia apart from that which accompanies early pregnancy. The nausea is often described as "coming in waves." It is usually associated with a poor appetite, whereas the more painful and flatulent "gall-stone" dyspepsias are compatible with a healthy appetite. The radiographic and test-meal findings, as suggested, are probably to be related to the physical type and gastric habitus of the individual, but the presence or absence of debility from auto-intoxication must be taken into account. According to Bonar,[13] achlorhydria occurs in 49 per cent. of cases of chronic gall-bladder disease coming to operation. Of the remainder of his series 29 per cent. showed normal curves and 23 per cent. hyperchlorhydria. He does not indicate what proportion of these cases were "dyspeptics."

Chronic appendicitis may or may not give rise to dyspeptic symptoms. Appendicular dyspepsia simulates both gastric and duodenal ulcer, the nature of the response again being determined by the normal habitus of the stomach and the presence or absence of auto-intoxication. The pain does not as a rule show such clearly defined characters as in ulcer and its relation to food is less constant. Radiographic and test-meal reports are of small diagnostic value, but with the test-meal there is found a greater liability both to hyperchlorhydria and to achlorhydria than obtains in a healthy series. In chronic appendicular disease without dyspepsia Bonar[13] found achlorhydria and hypochlorhydria in 55 per cent., normal acidity in 15 per cent., and high acidity in 30 per cent. In appendicular dyspepsia, however, 12 per cent. showed normal acidity and 88 per cent. hyperacidity with curves of the "duodenal type" in more than half the cases. Needless to say, the ultimate diagnosis, both in "gall-bladder" and "appendicular" dyspepsia, depends as much upon the direct and referred somatic signs of local disease as upon the reflex gastric phenomena.

CHART 16.



Duodenal ulcer with normal emptying rate and continued secretion.

According to Hurst,[14] patients with duodenal ulcer have stomachs of the hypersthenic type before they acquire their disease, and certainly the hypersthenic characters persist after healing of the ulcer. But in view of the fact that other and more distant lesions which can hardly be attributed to the hypersthenic diathesis are frequently found in association with hypertonus and hyperchlorhydria, it is also necessary to consider whether the gastric type may in some cases or some degree be determined by reflex stimuli from these lesions. The following figures from a small series studied by Dr. T. W. Turner and Dr. P. J. Briggs (communicated) suggest that the liability to hypertonus and hyperchlorhydria is greater with lesions below the pylorus, and that lesions above this sphincter influence gastric tonus and acidity in only a very small degree (Table VII.).

TABLE VII.—(*Turner and Briggs.*)

Disease.	Percentages (nearest whole figure).		
	Hypertonus.	Normal tonus.	Hypotonus.
Duodenal ulcer (50 cases) ..	43	55	2
Gall-stones and cholecystitis (44 cases)	21	76	3
Appendicitis (31 cases) ..	22	69	9
Gastric ulcer (16 cases) ..	13	67	20
Normal (Moody, Van Nuys, & Chamberlain) both sexes	12	78	10
	Hyperchlorhydria.	Normal curves.	Hypochlorhydria.
Duodenal ulcer (50 cases) ..	68	28	4
Gall-stones and cholecystitis (44 cases)	21	66	13
Appendicitis (31 cases) ..	19	75	6
Gastric ulcer (16 cases) ..	13	75	12
Normal (Bennett and Ryle) (males only)	15	80	5

The following cases illustrate types of dyspepsia produced by other forms of remote peripheral irritation.

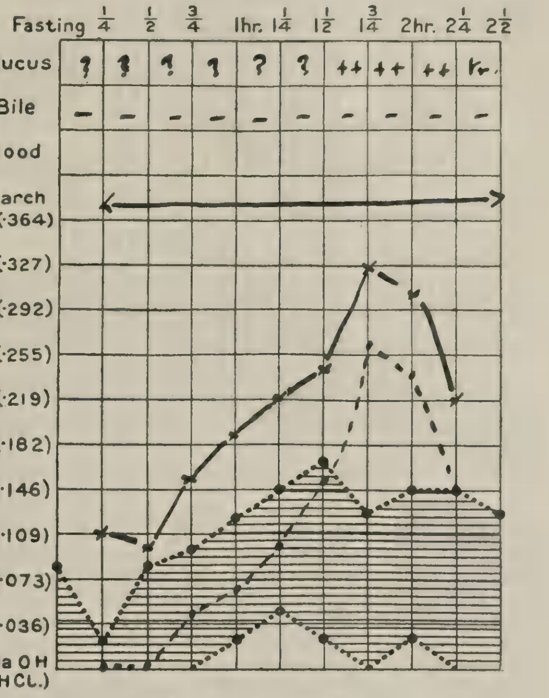
Irritative Dyspepsia Produced by a Fatty Epigastric Hernia. An old soldier, aged 52, complained of epigastric pain which had troubled him for three years, but which was becoming much more severe. The pain came on two to three hours after food and was relieved by food and hot water. He also had night pain. He had lost two to three stone in weight, and had particularly noticed that the action of stooping to lace his boots induced pain. There was a point of acute tenderness in mid-epigastrium. At this point a small fatty hernia through the linea alba was discovered which gave a slight impulse on coughing. The radiologist, Mr. Magnus Redding, reported a hypertonic stomach and spasm in the pyloric region. Mr. E. G. Slesinger operated and removed a protrusion of extraperitoneal fat which was causing tension upon and dimpling of the parietal peritoneum. The abdomen was simultaneously explored and no lesion of stomach, duodenum, gall-bladder, or appendix was revealed. The patient experienced no further symptoms and gained a stone in weight in the first month.

The extraperitoneal layer, of all the somatic tissues, is the one which becomes most sensitive in peptic ulcer, so the case further exemplifies the reversibility of the viscero-sensory reflex—a painful stimulation of the parietes, in this instance—calling forth painful contractions of the stomach.

In the special sense disturbances there is a particular liability to nausea and sickness as exemplified in the following case of ocular dyspepsia, and in migraine and Ménière's disease. They therefore constitute an exception to the rule that peripheral irritation produces "pressor" effects.

Ocular Dyspepsia.—A woman, aged 27, conscientious and of nervous habit, consulted me for attacks of nausea together with a certain amount of "indigestion" and flatulence. There had been a tendency to "sick attacks" in childhood, especially when she went to parties, but she remained free from symptoms between the ages of 8 and 20. The attacks complained of lasted from one to four days and were sometimes accompanied by a mild diarrhœa. They occurred at, roughly, three-weekly intervals and particularly on Sundays. The symptoms were usually most troublesome about an hour after breakfast or tea. She had a good colour, was not anæmic, and the physical examination showed nothing abnormal. Her eyes had been tested when the attacks began and were then pronounced normal. An initial rest from work and general hygienic measures gave no relief. Radiographic and chemical investigations were negative. The attacks became more frequent and she had to give up her work as a teacher. Finally, on re-interrogation she admitted to slight mistiness of vision and headache during the attacks. Mr. A. W. Ormond examined her eyes, found well-marked astigmatism, and prescribed appropriate lenses. In the next four months she had only one slight attack, reported herself as "ever so much better and stronger," and for some two years later has remained well. Headache was never a prominent symptom and there was no teichopsia, but obviously the case belongs to the same class as the migrainous dyspepsias.

CHART 17.



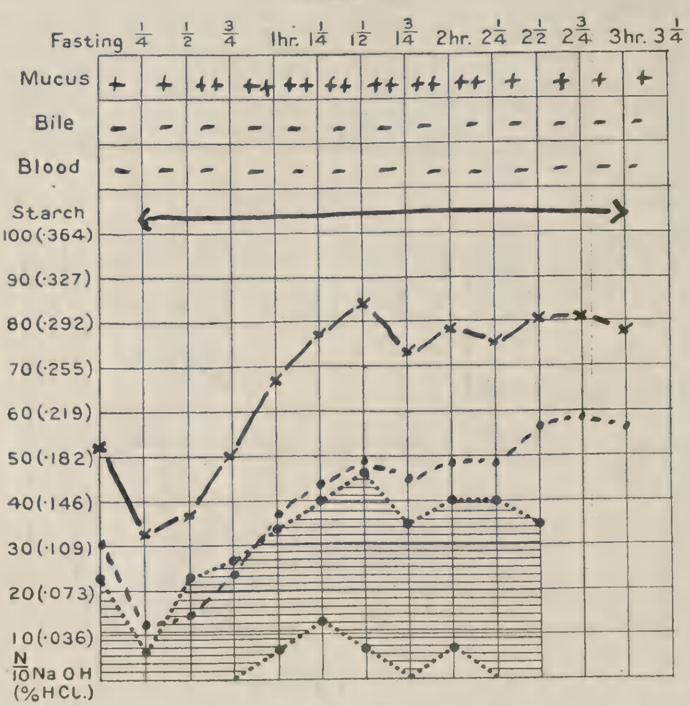
From a case of tabes with frequent gastric crises.

Tabetic Dyspepsia.—I have had no opportunity of close study of the disturbances of gastric function accompanying tabetic crises. Dr. C. P. Symonds tells me that he has observed the stomach with X rays after an opaque meal during a tabetic crisis and that peristalsis was greatly exaggerated. The severity of the pain in some cases; the persistence of the vomiting, often without much pain, in others; the abrupt arrival of the attacks at longer or shorter intervals without obvious reason and with no clear relation to food, occupation, fatigue, or other external circumstances are among the leading characteristics. Chart 17 was obtained between crises, which were occurring at very frequent intervals, from the only tabetic patient on whom I have had the opportunity of performing a gastric analysis at a time when gastric symptoms were predominant. The climbing curve suggests pyloric hypertonus.

5. MECHANICAL DYSPEPSIAS.

(i.) *Pyloric Stenosis and Obstructive Gastric Carcinoma.*—When stenosis develops from cicatrisation of a duodenal ulcer there is a change in the character of the symptoms. Patients with pyloric stenosis (or obstruction) frequently state that their food "seems to stick" or "will not move on." To this curiously accurate interpretation of sensations due importance should always be attached. In the early phases there is a severe recurring pain associated with increasing peristaltic vigour. At a later stage, however, vigorous peristalsis may be observed through the abdominal wall without any apparent association of pain, and by the time copious vomiting has become a symptom there may be periods of remarkable freedom from pain. It would seem that the muscle-fibre, by the hypertrophy which occurs in response to over-use, renders itself less liable to fatigue and pain, much in the same way as a skeletal muscle becomes able to perform without abnormal sensations an effort previously only performed with distress. When dilatation finally ensues and the muscle-fibre is stretched the hypertonus and hyperperistalsis previously contributing to the production of pain are no longer present. As dilatation increases, the vomiting becomes more profuse and there may be intervals between the attacks of many days. Malodorous eructations, particularly after certain protein foods, are present at this stage, and such signs as the succussion splash and recognition of food taken long previously complete the picture. The radiographic signs need not again be mentioned. Charts 18 and 19 illustrate the results of fractional analysis in cases of pyloric stenosis from ulcer and pyloric obstruction from growth. The interval between free and total acidity in the case of obstructive carcinoma is much greater than is the interval observed in health, in pyloric stenosis, in simple achlorhydria, or in achylia, and is only comparable with that obtained after a protein test-meal. Graham[15] showed an increase in the mineral chlorides in gastric carcinoma, a change which he attributed to the neutralisation of acidity by alkaline exudations from the ulcerated surface of the growth. Before the introduction of the fractional test-meal this increase in the mineral chlorides in the single specimen obtained by the Ewald method was an important sign and much more significant than the reduction in acidity. Bennett[16] has shown that if the stomach is washed out in cases of obstructive pyloric carcinoma, normal curves of acidity can be obtained; he has also advocated the administration of charcoal overnight in suspected cases, and states that recovery of the charcoal in the first specimen, even though there is no gross stagnation of food, is suggestive of delayed evacuation and, in association with the chemical and physical characters of the first and subsequent specimens, may help in the early recognition of the disease. As I have suggested elsewhere,[17] close observation of the physical characters of fractional specimens may be of greater diagnostic value than estimations of the acidity. Whenever possible the physician, even if he does not carry out the actual analyses, should see the specimens himself and note their appearance, odour, mucus, and bile content, the presence or absence of blood, and the quantity of the fasting and final specimens. These observations are as much a part of the clinical investigation as the inspection of the vomitus or dejecta.

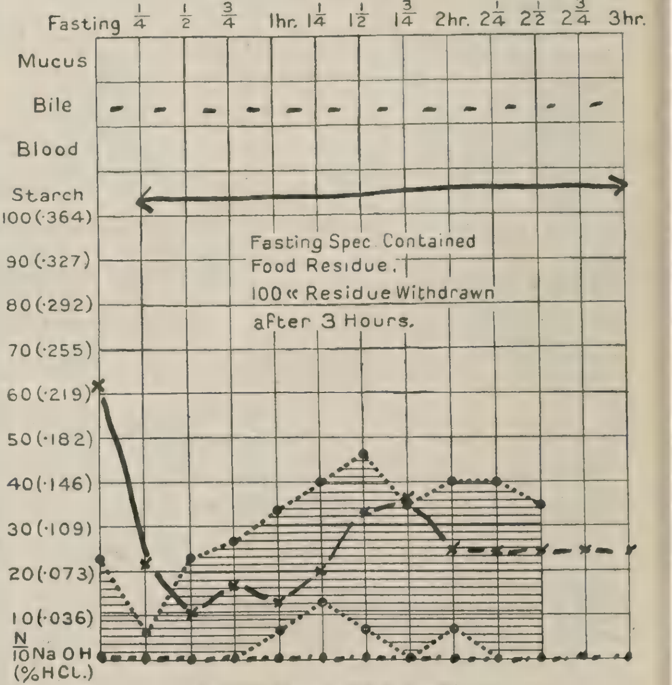
CHART 18.



Pyloric stenosis (ulcer).

Hour-glass Stomach.—The symptoms of hour-glass contraction of the stomach are those of chronic ulcer of the lesser curvature with the addition of obstructive symptoms. The distended proximal segment may sometimes be seen through the abdominal wall or may be brought into evidence by an effervescing draught, but the diagnosis nowadays is most readily made by an X ray examination. Hypochlorhydric curves are obtained excepting in the presence of pyloric stenosis, when hyperchlorhydria is the rule.

CHART 19.



Pyloric obstruction (growth).

The gastric symptoms of *Non-obstructive Carcinoma of the Stomach* are variable and depend largely upon the situation, character, and extent of the disease. The pain, when present, is more constant and often more severe than ulcer pain and is immediately aggravated by food. The frequency of anorexia has already been stressed. In some degree the dyspeptic responses even in carcinoma ventriculi may be determined by the physiological habitus of the stomach. I have in the past few months seen two cases of gastric carcinoma with a syndrome almost typical of duodenal ulcer. In both cases the patients were of the hypersthenic type, broad-chested and with a wide epigastric angle, and the pylorus itself was not involved. Achlorhydria, the development of which in association with carcinoma of the stomach was first shown by Golding Bird[18] in 1842, is less constant in non-obstructive than in obstructive carcinoma of the stomach, but it is generally found in diffuse carcinoma of the "leather-bottle" type.

I have reserved until the last a discussion of the derangements of function which follow upon the common operation of gastro-jejunostomy for ulcer and upon the complications attendant upon it.

An Address

ON

SUGGESTION IN SOCIAL LIFE.

Delivered at St. Bartholomew's Hospital, under the auspices of the Guild of Public Pharmacists, on Jan. 15th, 1925, with Lord Stanmore, Treasurer of St. Bartholomew's Hospital, in the chair,

BY SIR ROBERT ARMSTRONG-JONES, M.D., D.SC., F.R.C.P. LOND.,

CONSULTING PHYSICIAN TO ST. BARTHOLOMEW'S HOSPITAL IN PSYCHOLOGICAL MEDICINE; LORD CHANCELLOR'S VISITOR IN LUNACY; FORMERLY LIEUT.-COL. R.A.M.C. (TEMP.); AND CONSULTING PHYSICIAN IN MENTAL DISEASES TO THE LONDON AND ALDERSHOT COMMANDS.

MY LORD, LADIES, AND GENTLEMEN,—In the first place let me express my sincere thanks for the compliment paid to me in asking me to address the Guild of Pharmacists, comprising, as I understand it does, the representative organisation of all pharmacists holding appointments in H.M.'s Services, as well as pharmacists serving in hospitals, infirmaries, and dispensaries.

It is difficult adequately to appreciate as they should be the necessary qualifications of the modern pharmacist without a feeling of wonder at his efficiency, and it is clear that he, of the future, will have a much more complicated list of subjects to master than his predecessors have had, and for this responsible duty he must possess a mind above the average order if he is to prove a competent pharmacist. I looked up the meaning of this word in the new Oxford Dictionary and I find it means one who prepares and dispenses medicines, pharmacy being described as a medicinal potion, but I think this meaning too narrow, for let me state here that the remedies the pharmacist is called upon to dispense are by no means the complete and final agents in the cure of disease: for the chief and proximate agent is the subtle, elusive, but yet definite powerful influence of one mind upon another—i.e., the power of suggestion—which in psychology is a mental process by which an idea becomes an act—in other words, the transformation of an idea into an act. The remedy is dispensed and taken in the firm faith, belief, and hope of a cure, the idea of recovery and restoration is believed in, it may be logical or illogical, but through suggestion the idea is apprehended as the means to secure health, and in this wonderful influence of suggestion the work of the pharmacist plays a considerable part. The value of the pill or the potion, the tabloid or the tincture is considerably enhanced by suggestion. The facility with which suggestion acts depends greatly upon the fashion or vogue which appertains to things at the particular time, and we shall see later that imitation plays its part in the influence of suggestion, and some knowledge of the mind is therefore necessary in order to understand how suggestion operates.

POPULARITY OF THE STUDY OF PSYCHOLOGY.

For this reason, and after some deliberation, I decided to take as my subject some aspect of the Mind, which is the inner experience relating to the feelings, to ideas, and to the power we have to react to these by the efforts of the Will, and I am strengthened in my decision by the fact that of late there has been a very great interest taken in problems of the mind, more especially since the war, and in the direction of studying mental suggestion. Ordinarily the term suggestion implies that one idea will recall another to the mind which has been previously associated with it, but throughout this paper I shall use suggestion as any idea which is followed by action, not necessarily when the person is conscious of it and not necessarily an act of the Will or Volition. Indeed, this result may take place under different degrees of consciousness, that is during the waking period, in partial sleep, or during the hypnotic state. It is for such reasons that the study of psychology has become so popular, and we probably tend, more than in the past, to examine into our own minds, a process called "introspection." We certainly tend more often to look into other people's minds, and by the process of "interpretation" draw inferences and reach conclusions not always too complimentary or fair to the objects of our experiments. It is not improbable that before long no one will be permitted to have a banking account unless he has satisfied a standard test at some psychotechnical laboratory. At any rate, there has been a revived interest in mental problems, as to how ideas have arisen and whither they tend. We are anxious to see how our ideas are sorted and arranged, how they combine to form motives, how motives may be analysed, and how behaviour and conduct are directed and controlled. It is claimed for this study that psychology has already helped to make child-life interesting, if not fascinating; that the dullest novel can be read with pleasure, and that bores when psychologically presented may be transformed into the most engaging personalities. As to this added interest in psychology let me use a simile—viz., the motor-car. No driver would ever dream of using a machine without first finding out something about its mechanism and how it worked. If he neglected this modest preliminary study, several interesting things might happen; perhaps the car would not start, or if it started perhaps it would not stop, and the driver (or if he carried passengers, he and they) would soon experience thrills, to say the least; yet, in the study of the Mind many who claim to possess one are perfectly heedless about its mechanism, although the mind is much more complicated, and, may I add, more interesting also, than the motor-car. Fortunately for most of us, the human mind is to a great extent self-acting, but sometimes the mind does go wrong; indeed, it is only too surprising, considering it has about 9000 millions of neurons or nerve-cells in an average brain, that it so seldom goes wrong; yet when the mind is looked after and is attended to until it is understood, it is capable of superlative achievements, for it can carry us into great positions of power and distinction, and enable us to maintain these in spite of acute competition for a place in the sun. The advantages of an elementary knowledge of psychology are therefore clear; it enables each of us to understand our own mind, and how it works, as also that of our competitor, the practical result being to save us endless trouble in the acquisition of knowledge and in its application when acquired, although, luckily, many of us do manage without special study to acquire some knowledge of the working of our minds empirically (Glover) and also to attain comparative success. When our minds are managed rightly and our thoughts are arranged in an orderly and methodical way, we are enabled more easily to follow our various occupations, to find more pleasure in our work, to use our leisure more happily, to select the best companions, even a husband or a wife. We also learn to control our will-power and so to make resolution strong and temptation weak. Indeed it is difficult to see how we can advance at all without some knowledge of psychology. Pope maintained that the proper study of mankind was man and that the chief thing in man was Mind.

ELEMENTARY SENSATIONS.

Like the material world which is made up of atoms and electrons, the mind is also made up of elementary sensations—hearing, sight, taste, smell, and touch. Sensations are the most elementary mental processes we can experience, and they are incapable of being further split up even by the most persistent introspection or examination of our own minds, but pure sensations are only possible during earliest infancy, for we soon begin to think not in atoms as it were, but in molecules; our sensations tend to be associated together and with other things, so that sensations become percepts, which is the next mental process in development and an active one. The various sensations, therefore, coalesce and merge into a united whole, giving us the percept—e.g., the buttercup is not only yellow, it is form, size, touch, and feeling; its acrid taste is also "associated" with it, in other words; it is now a percept and no longer a simple sensation of yellow, but we can proceed further in our mental evolution and we can recall the flower in its absence which gives us the image, or the idea of the flower, and we can proceed further still, for we can in imagination group these flowers into classes or form concepts of them. Such a process as this is abstraction, and is the constructive work of the genius who out of different groups of ideas constructs new combinations, new mechanisms, new plots for stories, poems, pictures, and great original works of art. We should therefore all try to cultivate our senses, be precise and accurate in our percepts, form the habit of appreciating clear ideas of percepts and group our ideas into concepts, and from these construct new synthetical groups or classes. Such a study is the high road to a well-developed mentality, to the full realisation of self, and to the final achievement of our ambitions, aspirations, and aims.

IDEAS ANALYSED.

It is an ascertained fact in psychology that only a few of the many ideas experienced or combined can be in our mind at any particular moment—i.e., can be attended to in the focus of consciousness, because this focus of the attention is a very limited field, and if we analyse our own minds at this moment —or now—our ideas would probably come under five heads:—

1. Impressions of things around us in this great hall with its interesting records.
2. Some bodily or other sensation—e.g., from sitting on hard chairs, or in cold corners.
3. Some memories of past events, such as last week's clever performances here.
4. Some feeling of pleasure, or the reverse.
5. Some promptings of the Will, which are either to sit still and listen, to make some apt or inapt comment, to express approval, or to pick up our hats and walk out.

These would be in the focus. All other ideas would be outside the focus, or threshold of consciousness; they might perhaps be on the verge of this field in the subconscious mind and liable to be recalled, for our subconscious minds are the parts out of which ideas are recruited by an effort of the Will; on the other hand, they may be quite inaccessible, because buried in the unconscious mind, which, as stated, we all possess. We know, or our intimate friends know, that under certain sets of circumstances we would act in a certain way—that is, our inherited traditions, our upbringing, education, and surroundings have already unconsciously formed our "bias," for we each of us has certain leanings, a certain "bias" of which we may not be conscious; yet we realise that it somehow or other unconsciously influences our tendencies to act. We cannot, therefore, too highly value the very great importance of good traditions—such as we possess here—the good education and good surroundings which together unconsciously help to make, in our own profession, what is euphemistically described as the best type of doctor—viz., the Bart.'s man. Consequently, I cannot too forcibly demonstrate to you these three layers of the mind—viz., the conscious, the subconscious, and the unconscious mind—upon each of which suggestions can act. The violinist plays, but is not conscious of reading the notes. I walk along a rough road, and unconsciously avoid obstacles. The organs in our bodies work unconsciously as do most of our reflexes, and if consciousness were our only mental life it would indeed be a poor and narrow one.

It is an extraordinary thing, but still a truth, that all ideas in the mind exist in a perfectly chaotic, confused mass, until summoned into order by the attention. They are all struggling together in competition to get into the field of attention, they are all striving to cross the threshold and to reach the focus, or as it has been also called, the dome of the mind. All ideas tend, if they can, to rise to the top of the dome, which they are more likely to do if they are linked up with some pleasurable feeling or an emotion, for we tend to retain happy thoughts and to cast out or to repress the opposite, hence the importance of cultivating the happy side of life, for happy suggestions tend to raise and exalt all the vital functions; they tend to quicken that inherent tendency to the normal which is characteristic of all living tissues; that disposition towards health or that equilibrium which doctors describe as the *vis medicatrix naturæ* and which is always sensitive to suggestion, good or bad. It is a fact that once ideas get into the dome of the mind, or into the focus of consciousness, they become distinct and clear, because the attention or the will is fixed upon them, but even when within the dome they cannot be kept there, they soon pass out again to give place to other ideas, and it is stated that no group of ideas can remain in the focus of attention for more than 30 seconds.

It is because of this constant current of ideas to reach the dome that the Mind has been compared to a stream, always coming and going, always flowing. Many ideas are too feeble ever to reach the dome, and it is only the emotional tinge—the fear, the hope, the hatred or love, or the pleasurable sensation—

attached to the idea that secures its arrival into the focus of consciousness. Ideas are not socialists, they hate equality; they are constantly and continuously competing and struggling to reach the dome, and it is clear therefore that a suggestion made to the mind with its appropriate feeling may reach the summit if the feeling attached to it is sufficiently strong. An inscription over the entrance into our school buildings, "Whatsoever thy hand findeth to do, do it with thy might," is a suitable suggestion to reach the dome, and success depends on the feeling attached to it and its application.

THE ACT OF REASONING.

Although ideas in the mind, until focused, are confused and chaotic they nevertheless do tend, of their own accord, to assort themselves, but only according to certain laws; for instance, those that are similar tend by their similarity to be grouped together—e.g., a cross-Channel passage suggests certain unpleasant sensations felt on a similar previous trip; a political meeting suggests disharmony, if not rowdiness, which occurred on a similar occasion elsewhere; and Harley Street suggests eminent doctors, for we knew at least one there. Also, those ideas that have occurred together in point of time tend to be associated by "contiguity"—e.g., picking primroses suggests early spring; an acid and alkali together will burst the stoppered phial, and to suggest their association is to expect a calamity; to be stopped on a clear road by a policeman when motoring suggests the question of speed limit, for the event has occurred before. We cannot have ideas without feelings, and with them a time element or a likeness to others, for they must first be judged or cognised, which is an act of the Reason. In Reasoning we pass from one judgment to another deductively when we reason from general principles to particular cases. It is the work of the Reason to criticise and to compare ideas, but the Reason is much influenced by the feeling associated with them, in other words, by their affective tone—i.e., whether such ideas be pleasurable or painful.

WILL-POWER.

There is one other element of the Mind beside the feelings or sensations, and the Reason, which we have not considered, yet it is the most important of all; indeed, it is the only one that differentiates man from the lower animals. This is the Will, the power of inhibition, of self-control, the power to say "No!" It is by the exercise of this faculty that man can claim to rise to a higher sphere of action and conduct. It is the Will that suppresses the passions, that governs the instincts, and controls the emotions associated with our perceptions, ideas, and concepts, and so prevents their exercising an undue influence over our actions. It is the Will that collects the momentary sense impressions, the fleeting ideas that pass in the flowing stream, of the mind, and it is the Will that collects the memory pictures stored up in the brain cells and brings them into the focus or the dome of attention. In the whole mental field it is the Will which occupies the sole directing position. For instance, when preparing this paper I had to fix my attention, to experience many struggles in order to exclude distracting ideas, and to prevent my mind from wandering into other channels. At times I had to use a mental effort to keep my attention fixed on my subject and so complete the task I set myself to perform. It was a conscious effort, but it was essential that I should finish my task; and the conscious effort was the measure of my Will-power or of my volitional exercise. In the opinion of competent psychologists there is still another source of action in addition to and apart from the Will, and that is the power of suggestion, which arises from an idea within the Mind. The starting point of suggestion is some idea, which may not be apprehended by the conscious mind, but if it is, it then becomes a "direct" suggestion; the clergyman in the pulpit makes a direct exhortation or suggestion to his congregation, the surgeon advises an operation, or M. Coué commands his patient to repeat he is every day getting better and better; and when I present a complicated prescription to the pharmacist it is a case of direct suggestion that I want it dispensed, it is a transformation of an idea into an act, and the suggestion may be our own from within (auto-suggestion) or through others from without (hetero-suggestion), yet even a hetero-suggestion becomes an auto-suggestion in the end.

"DIRECT" AND "INDIRECT" SUGGESTIONS.

As we know, the Will and the Reason exercise an inhibitive or a controlling power over suggestions: it is, indeed, the whole aim of education to control and direct the mind and so to prevent irrelevant suggestions from intruding upon it. Thus there is always a struggle between the orderly control of the Will and the sudden impulse to act on suggestions. The influence of "direct" suggestion is less powerful than is that of "indirect" suggestion which occurs when the mind is at rest or inactive; indeed, when the mind is fully occupied and engrossed it is difficult to get any direct suggestions to act, as is recorded of the philosopher whose wife was about to present him with an addition to their happiness, for when the nurse announced, "Please Sir, it's a boy," he coolly replied, "Ask him what he wants, I am busy," and later when the nurse called out, "Your wife is dying, Sir," he replied, "Tell her to wait till I come"; or as was the case with another searcher after truth who was equally engrossed in his meditations, when the messenger rushed in with the alarming news that the house was on fire, he calmly requested the messenger to convey the news to his wife, as he never interfered in domestic affairs. These, and stories of men in action being so overwhelmed with mental excitement as not to know they were wounded, show that when the Mind is fully absorbed suggestion acts with difficulty, there is no room for distracting thoughts from without; but when the mental tension is relaxed the influence of suggestion is exceedingly strong, for the imagination then runs riot, the Will and the Reason are both suspended, and the Mind is free to wander in obedience to half-conscious suggestions. In mental states of reverie, "mooning," or abstraction, the mind is in a suggestible state ready for new ideas to be presented. Children when playing games are thus suggestible and are being unconsciously moulded in conduct and character every minute, and therefore good suggestions by example and precept are most important, which supports the view of the Jesuit, that if he had the care of the child for the first seven years, anyone can have it afterwards; implying that unconscious suggestion would by then have become so organised that no subsequent influences could neutralise those from early teaching. Such "indirect" suggestions made in infancy leave indelible traces on the mind, which is "wax to receive and marble to retain," and so, impressions of training once received in early life have the quality of permanence; nevertheless, we are unconscious of them, as they do not ordinarily reach the conscious mind; but yet, in spite of this, they form the trend or tendency or bias of the individual in later life, and it is upon the indirect influence of early suggestions that the permanent conduct depends. The periods just before sleep or just before awaking are the most favourable to suggestion, as we know ghost stories are more readily believed in towards the hour of sleep, partly because suggestibility is most marked at the period of approaching sleep and partly also because of the state of fatigue then felt, when there is less vigour to resist suggestion. It is claimed that suggestions from the mother repeated nightly whilst the child is being put to sleep must bear good fruit in after life. Sleep is not necessary to suggestibility, it only facilitates it; as we know to be the case in the hypnotic state, which is one of artificial sleep. Some of us may have suddenly awaked from sleep and felt we had lost our way in a strange place and we have got up under the influence of this suggestion and searched for aid; and it is a fact that some persons under the influence of suggestion during sleep have been able to solve problems that have bewildered them when awake. In illness it is the same, and advantage is then taken of this readiness to receive suggestions, to create an impression upon the patient by the solemn manner of the doctor, whilst his top hat, and the mysterious and horrid medicine in formal bottles help the suggestion of impressiveness. All doctors know the value of suggestion in the treatment of disease, and a classic case was that recorded by Sir James Paget—a name greatly revered in this school. This patient's mother who brought her told the great surgeon "She will not walk." The patient said, "I cannot walk"; but Sir James Paget summarised the truth by saying, the fact is "she cannot Will"—i.e., until the weakened will-power was strengthened by belief in the cure, she could not recover, but would continue helpless until suggestion presented the idea of recovery and this, with its emotion, would rouse the latent power into action. In the mental out-patient department at this hospital a paralysed lame girl was at once cured by suggestion.

During the war a soldier who had been blind for months regained his sight at once when the suggestion was convincingly made to him that he would see. Many aphonic soldiers and several who were deaf, from functional lesions, were immediately cured, as also many who were helpless and paralysed; and our case-books have many records of such cures by the influence of suggestion. It is useless as well as unkind to tell a person who cannot cross the street, or remain in a closed room, or who believes himself to be paralysed that he can be well if he chooses and that his malady is an imagined one. He will only conclude his case is not understood and he will go away worse than he came. He will probably go away also in the firm belief that his case is incurable and chronic and that he himself has been regarded as a shammer and a malingerer. No appeal to his conscious reason will be of any avail, but suggestive treatment to his subconscious mind will cure him at once.

"Prestige" Suggestion.

The influence of suggestion coming from a great institution of authority such as Bart.'s, with its great traditions of the past, and the present accumulated wisdom and knowledge of skilled teachers such as we possess here, gives to the treatment of the patients in this hospital what is described as "prestige suggestion," and is an undoubted aid to the healing powers so successfully employed here. It is not only the students that are impressed by this, but the physicians and surgeons must also profit by these suggestions. The same kind of influence acts as a source of great power when emanating from high social rank, or from some great source of mental ability, or some marked physical strength, or from some other great power; hence the influence of the Deity when invoked in the work of spiritual healing, as we have lately seen, will help considerably by suggestion, and will add to the number and permanence of the cures. My influence will probably disappear when I have withdrawn, but the influence of the Deity will remain. States of mind described as "day-dreaming" or "castle-building in Spain" are half-awake conditions, and thoughts or ideas suggested to the Mind in these states are accepted as a normal experience and believed in because there is a partial suspension of the Reason and the Will, and therefore there is no voluntary direction to change these ideas in the Mind, which comes to be entirely dominated by them, the more so when there is with the suggestion a belief and a faith together with an expectant attitude, as in spiritual healing. There is here the feeling that the result anticipated must be accomplished. The attitude of expectancy greatly intensifies the power of suggestion.

Repetition.

Another condition favouring the influence of suggestion is repetition. George IV. repeated the statement so often that he was present at the Battle of Waterloo that in the end he came to believe it, and no argument to the contrary would convince him he was in error. An Oxford graduate used to walk regularly in Hyde Park when the auto-suggestion came to him that he should knock off people's top hats. He realised that it was an unconventional act and was impolitic and would be mildly resented, but the suggestion was so strong, relentless, and tyrannical, and it was so dominating and persistent that he felt it was wrong to resist it, with the result that he was brought to me at Claybury, and his case is probably familiar to many old Bart.'s men. As to dominating ideas, which are extreme cases of auto-suggestion, every asylum has its kings, queens, peers, and others because the ideas suggested are in harmony with their own mental trends or tendencies, and no persuasion can dispossess these persons of their dominant ideas. In insanity the Will and the Reason are no longer able to command the thoughts, and therefore the Mind cannot judge or compare what is brought before it, whilst in the awakening from hypnotism the spell of the suggestion has been withdrawn. Sometimes suggestion is carried too far and the reverse or the counter-suggestion may be acted upon. Instead of the normal response to the stimulus, other stimuli contribute to the response, and the natural response to the suggestion is inhibited. The opposed ones upset the balance and the opposite of the suggestion occurs, because the response is not the result of the total of relevant stimuli, and so the suggested stimulus is inhibited. We all know the "cussed" fellow who when advised to avoid certain foods yet eats to his detriment, or when advised to take a holiday replies he does not need one. He takes a pride in doing the opposite to what is suggested, and often defies custom and ceremony. Such persons obey the "law of reverse effort," as M. Coué says, and they constitute our eccentrics, oddities, and singularities. Everybody knows that a committee or a board is a mathematical paradox: its collective wisdom is known to be less than the total of its individual members, yet what security is often erroneously conveyed to possible shareholders by suggestion when a long list of names figure on a prospectus, which would otherwise go into the waste-paper basket. The "prestige" suggestion counts for much here.

"Crowd" Suggestion.

The crowd suggestion or mass suggestion also exercises a great influence upon the mind. Crowds of people are very impressive, and crowds of names on a petition often count for much more influence than would the names separately. Also, witness the great power in healing the sick exercised by pilgrimages to Lourdes, Sienna, Assisi, and other places where there are relics of the saints; and at Holywell in our own country; yet the proportion of cures is less than 5 per cent.—some say less than 1 per cent.—and if these statistics were set forth as claims for support by the London hospitals, they would soon cease to be supported. You, as pharmacists, know the changes that fashion and custom have caused through suggestion in the use of medicines and therefore in dispensing. Formerly the prescriptions that were most effective were the most nauseous and the most repulsive; the worse the disease the more horrid the remedy. Each disease had its sign, and could only be cured by the administration of the remedy with the corresponding sign; for instance, certain plants that resembled the bodily organs contained the remedies for these by their similarity to them, the lungwort, liverwort, madwort, pilewort were so prescribed. For epilepsy, 300 years ago, then, as now, regarded as rarely curable, the best remedy was the dried and powdered remains of a female mole for a male epileptic, and a male mole for a female, to be taken when the moon was in the sign of Virgo, by which "much ease will result." For insanity the unfailing remedy consisted in injecting the juice of beet into the nostrils—probably a cure if it could ever be got up there. The plague was treated with a live pigeon cut in two parts and applied to the soles of the feet. The heart of a fowl, the liver of a mole, and the foot of a tortoise were probably the precursors of the poly-glandular tabloid and an anticipation of our present endocrine therapy. To-day the fashion is for vaccines, serums, and antitoxins, the blood being regarded as the great battle-field in which proteins and bacteria are contesting for a victory over globulins and precipitins—i.e., so long as the life of their host endured under the treatment.

GESTURES IN MEDICINE.

It must not be thought that we of to-day are free from "gestures" in medicine. Not long since it was suggested that human beings had in their natural evolution approached too near to the herbivora, and man's inside was too long. On the authority of a great surgeon everyone was advised to have his colon excised and his internal economy short-circuited, again transforming an idea into an act. The suggestion that persons should be divested of any part of the alimentary tube which had hitherto served to assimilate his nourishment did not receive a too cordial support and the vogue dropped. Fortunately, a more sensible view of the functions of the 32 feet of our inner tube was taken, but a new fashion was initiated—viz., intestinal antisepsis; and liquid paraffin became a popular remedy; so much so, it is stated, that shares in the Persian oil fields rose considerably in price on the Stock Exchange. How long the suggestion of internal lubricants or of intestinal disinfectants will last, it is not safe to predict: but it is certain that just as poly-pharmacy has had its day, so these suggestions, together with sandwiches of pancreas and endocrine preparations, may also have their day, and the treatment of the future may more and more tend to rely on common-sense to avoid "the first occasion of sickness," as the ancient physicians pronounced it, and "to take away the evil effects of the same," as was then taught, which is the encouragement of the *vis medicatrix naturæ*, or of the inherent tendency to get well that resides in every living tissue. At present some of the "colloids" are having a struggle to keep their places as fashionable remedies; but the latest suggestion in treatment is to provide a supply of vitamins, which have never yet been seen or separated by mortal man, yet they are resident in milk, vegetables, and fruit; and lest they be lost it will probably be suggested that man should once again reside in a garden and have his fruit and vegetables near, and also that his herd should be milked at his gate so that he should not lose the vitamins recommended to him. It must therefore not be assumed that we—of to-day—are free from using suggestions. The classic doctor in recent times was a bearded, middle-aged, grave, and pensive figure, sitting—as in Luke Fildes' picture—by the bedside of a sick child and more correctly holding a wooden stethoscope in his hand. To-day such a picture is out of date, being replaced either by an attractive lady or by a clean-shaven young man, dressed in tweeds, and holding in his hands not the stethoscope, but the hypodermic syringe and an ampoule, the up-to-date young physician duly deliberating how many cubic centimetres of detoxicated serum he contemplated injecting into his patient subcutaneously.

I am not certain whether the Freudian cult may not (according to Megaw) have suggested a still later picture of the doctor in which symbolism reigns supreme: the wooden stethoscope has now become a phallic emblem; the patient's attention is transferred to the analyst, whose position is also "father-confessor," the patient's mind, body (and estate) having been sublimated without resistance into his power. This picture may be further adorned by two statues erected to represent Œdipus Rex on one pedestal and the hypothetical Censor on another, both in perpetual conflict over the solution of a dream which is being dramatically related. The theme of this picture is "*cherchez la femme*"; a subject which has continuously, since the Trojan War, supplied material for the painter's canvas, but which of late has suffered an acute revival even in medicine.

SUGGESTION IN CLOTHES.

Possibly no suggestion is more powerful than the fashion set by clothes, and especially is this the case in our Western civilisation. Formerly clothes conveyed the distinction of a class and indicated rank. They therefore had to be distinct and striking. In this way they attracted attention and the clothes were probably admired. An old book on medicine, dated 1649, laid down as the duty of woman, "to serve God and to maintain man; to wear garments that were comely and strong—made to preserve health rather than to adorn the person." To-day things have changed, and a fashionably-dressed woman is no uncommon sight, for she is bound to attract attention and her clothes generally produce a powerful sensation, which can only be kept up by originality of design, and by some special style or new colour. A woman with a fashionable hat from Paris and stylishly dressed—however scantily or "cobwebby," or "feathery" this may be—is much happier and more self-confident than another who is dressed more healthily and more comfortably, but less fashionably, yet who is superciliously described by the others as a dowdy frump. Clothes more than anything else lose their attraction to their fashionable wearers when they become familiar and when they cease to produce a new sensation. So great to-day is the triumph of democracy that there is a marked tendency for the general adoption of one fashion by all classes; the only sign of rank and distinction being shown in the quality and cost of the materials selected. When clothing indicated occupation, they were voluntarily worn by such as the clergy and the nursing profession, as also by the representatives of the law. These upheld in their garb the high rank and dignity of their calling. The costume that indicates occupation tends to be resented to-day by such as are in domestic service, whilst the railway official, the postman, and the policeman still retain their distinctive garbs.

FOOD AND THE ARTS.

The fashion in food has also very considerably changed in recent periods; a variety of foods, rather than the *pièce de résistance*, is the fashion to-day.

The influence of suggestion extends even to the arts, as witness the interpretation of the beautiful and the true by the futurist and the cubist, who are extravagant and misguided representatives of the artistic set.

Suggestion plays a greater rôle in our lives than we imagine. It is the basis of imitation and so begins unconsciously in very early life. Its highest form and probably its most agreeable presentation is in the best actors on the stage, who pourtray by imitation the most perfect characters that can be suggested to us—or the reverse.

Low-class cinemas play a great part in suggesting assaults, malicious damage, and theft to the sensitive minds of young people, who are not criminals but only eager for adventure. Many instances are recorded in the daily papers. A youth took a knife and with it stabbed another boy, and the father stated "picture-houses are to blame for the whole thing." A Dalston boy witnessed a hanging incident. He went home and repeated the occurrence with a fatal result. A boy burgled at Upper Clapton and confessed to seeing the whole thing done throughout at what he called the "public picture gallery," and there is no possible doubt but that pictures thus presented exercise through suggestion a marked evil influence on conduct in the sensitive and impressionable minds of the young.

Conclusion.

May I conclude by saying that the moral of this paper is that good suggestions should be made to the child and the young, as they are then unconsciously accepted by them and thus they tend to form a good background, so that the child may act upon the suggestions reflected into its mind, and in consequence its trend or mental bias in after life may tend naturally and unconsciously towards actions that shall have a high ethical value.

The highest suggestion for conduct is to do what we ought to do, and moral education consists in creating a desire for right conduct. A child (as well as most young persons) is essentially governed by feeling and not by reason, therefore its present work should be associated with happiness—which is the "universal quest"—and an endeavour made to suggest altruism or a consideration for the good of others, that restrictions and rules are made for the general good and not for the individual only. Positive training is always better than negative training; a child or a youth is always open to tactful suggestions and much help can be secured from one successful effort towards self-control because he is then reassured he has made one good step in the way of directing his will and controlling his desires and thoughts, and so to supplement and strengthen the higher good within him.

I have been permitted to make a suggestion to my audience, viz., that each may take a special interest in psychology—i.e., in the working of the human mind. It is a study that will well repay attention even in leisure moments.

ON THE TOXIN OF STREPTOCOCCUS SCARLATINÆ.

By HERBERT HENRY, M.D. Lond.,
and
F. C. LEWIS, M.R.C.S. Eng.,
CITY BACTERIOLOGICAL LABORATORIES, BIRMINGHAM.

CITY FEVER HOSPITALS, BIRMINGHAM.

(*A Report to the Medical Research Council.*)

The ætiology of scarlet fever is a problem which has attracted the attention of bacteriologists over a period of many years, and, as research work has developed from time to time in various parts of the world, so there have arisen a number of theories in regard to the actual causative factor in the disease. For long, attention has been focused on the rôle of certain streptococci in this connexion, but it is only very recently that convincing experimental evidence has been brought forward in support of the view that streptococci have a definitely specific relationship to the disease.

The difficulty which workers in the past have had in establishing this relationship lies in the fact that it is not possible to produce in experimental animals a condition that in any way resembles the picture of scarlet fever as it occurs in man. Nor, as Hektoen[1] pointed out, had attempts at experimental inoculation of human beings with material taken from cases of scarlet fever proved successful till the published observations of Dick and Dick[2] in 1923. The first attempts made by these workers to produce scarlet fever in human volunteers were published by them in 1921[3] and proved to be unsuccessful, probably because they used individuals who were actually immune to the disease by reason of their being urban dwellers. In their second series of experiments in 1923,[2] acting on the suggestion made by Hektoen that individuals drawn from rural districts might be found to be more susceptible than town dwellers, the Dicks succeeded in producing one case of typical scarlet fever out of five volunteers. Each of these was inoculated by swabbing the throat and fauces with the culture of a streptococcus obtained from an infected wound on the finger of a nurse who developed scarlet fever while attending a case of the disease.

With a further series of volunteers the Dicks[4] showed that the culture filtrates they were using at the time produced no disease, whereas whole cultures did so, and they concluded from this finding that a filtrable virus could be excluded as a causative factor in scarlet fever. The same observers[5] further demonstrated that the streptococci which are associated with scarlet fever produce a soluble toxin, and that this, when inoculated into susceptible volunteers in suitable doses, is capable of giving rise to all the characteristic signs and symptoms of the disease. Moreover, weak solutions of the toxin[6] when injected intradermally—in much the same way as diphtheria toxin is used for the Schick test in diphtheria—produce in susceptible individuals a skin reaction which provides an empirical measure of susceptibility to scarlet fever. Of persons who had not suffered from scarlet fever 41·6 per cent. gave positive reactions, while negative or only faintly positive reactions were to be found in convalescent scarlet fever cases. This reaction is known as the Dick test. The results of the Dicks have been confirmed by other American workers, notably by Zingher.[7]

The work embodied in the present report represents an investigation of the toxin of *Streptococcus scarlatinæ*, more particularly with reference to the best methods of preparing it, and special attention has been devoted to the preparation of stable products by means of precipitation. These latter, we believe, represent the first step towards a successful measure of the toxin, and so offer a method of approach to a standard Dick test.

Our experiments are still actively in progress, but we believe it to be desirable at this juncture to put forward certain of our findings.

The Dick Test.

The Dick test consists in the intradermal inoculation of suitable dilutions of the toxin of *Streptococcus scarlatinæ*. The amount of inoculum consists of 0·1 c.cm. or 0·2 c.cm. A positive reaction indicates that the individual is presumably susceptible to scarlet fever, while a negative reaction yields evidence that the individual is immune to the disease. A positive reaction begins to appear within a few hours, usually four to six, after inoculation, and reaches its maximal development in about 24 hours. It is represented by a local area of redness, varying in size and in intensity of colour. This area has, as a rule, well-defined margins, but it may at times merge gradually into the surrounding skin. Where the reaction is intense in character it is accompanied by induration. At 48 hours from the time of inoculation most Dick reactions have disappeared completely or have faded considerably, while in the case of strong reactions there may be a residual pigmentation and peeling. It may be said, therefore, that the Dick reaction differs from the Schick reaction in that it appears rapidly, lasts for a short time, and then disappears leaving little or no trace behind.

In all cases it is necessary when testing Dick toxin to use a control. For this purpose we have had recourse to the same toxin heated to boiling for one to one and a half hours, as recommended by Zingher. In practice it is convenient to inoculate the toxin to be tested into the skin on the anterior aspect of one forearm, and to inoculate the heated control into a corresponding area on the other arm. Areas of redness measuring 1·0 cm. or more in diameter are interpreted as positive, while areas of lesser size are to be classified as faintly positive. Where the control shows no reaction there is no difficulty in interpreting results. If, however, there is a reaction on the control side—i.e., a pseudo-reaction—then the question of susceptibility or immunity resolves itself into a comparison of the two reactions. If the areas on both sides are equal, the reaction is pseudo-negative. If the reaction is larger with the unheated toxin, then it is described as pseudo-positive.

Preparation of Toxin.

The method of obtaining the toxin, as originally recommended by the Dicks, consists in the collection of condensation water from a series of inoculated sheep blood-agar slopes after varying periods of incubation. Other workers, including Williams and his colleagues,[8] have made use of horse-blood broth. Zingher[7] prepares the toxin from pneumococcus broth to which has been added 5 per cent. citrated horse blood. His cultures are incubated for five days, after which 0·5 per cent. carbolic acid is added, the resulting precipitate being allowed to settle out and the supernatant fluid being used for test purposes. Huntoon[9] obtained toxin most readily by using broth containing large amounts of horse blood, and by incubating the medium for seven days. To get rid of the foreign protein he acidifies the cultures with 1·0 per cent. acetic acid and then carries out a precipitation either with ammonium sulphate to 60 per cent. saturation or with sodium chloride to 20 per cent. saturation. In either case the resulting filtrate is dialysed before use.

The process which has given the best results in our hands is a modification of the original Dick method and is as follows. To trypsinised agar in the melted state and contained in a series of Roux bottles there is added fresh rabbit blood—1 per cent. to 2 per cent., or human pleuritic fluid—5 per cent. to 10 per cent. The medium after thorough mixing is allowed to set hard and the surface of the agar is then flooded with 2·0 c.cm. of a young broth culture of *Streptococcus scarlatinæ*. The strain of organism we have used is the Dick-Dochez strain from the National Collection of Type Cultures. After 18 to 24 hours' incubation there is added to each Roux bottle 5·0 c.cm. of carbol saline. It is possible by gently rolling this amount of carbol saline over the surface to collect as a dense suspension the whole floating growth from the surface of the agar. The total amount of fluid in the bottle is then removed by decantation. The pooled contents of a series of Roux bottles is then centrifuged at high speed, when the streptococci come down as a dense cake; while the supernatant fluid is passed through a Berkefeld filter, tested for sterility, and finally put up in suitable dilutions for the skin test. Specimens of toxin prepared in this way, which has the merit of simplicity, have been found to give good Dick reactions in dilutions of 1 in 2000 up to 1 in 30,000. In our experience toxin taken from Roux bottles incubated for longer periods does not reach such high titres, and we believe that it is in the short period of incubation that the efficacy of the method resides. Another advantage of toxin prepared in this manner consists in the fact that it but rarely gives rise to pseudo-reactions.

Precipitation of Toxin of Streptococcus Scarlatinæ.

The toxin of *Streptococcus scarlatinæ* can be precipitated out of condensation water preparations by means of alcohol.

Experiment I.

A condensation water toxin was tested out on a selected series of cases in dilutions of 1 in 5000 and 1 in 10,000. The results were as follows:—

	Positive.	Negative.
Toxin 1 in 5000—		
Non-scarlet	3	–
Scarlet	1	3
Toxin 1 in 10,000 —		
Non-scarlet	2	3
Scarlet	–	5

Eight volumes of alcohol were then added to this toxin. The resulting precipitate was separated by centrifuging, re-dissolved in carbol saline, and made up to its original volume. The result of skin tests with dilutions of this toxin was as follows:—

	Positive.	Negative.
Toxin 1 in 4000—		
Non-scarlet	7	–
Scarlet	5	5
Toxin 1 in 5000—		
Non-scarlet	3	–
Scarlet	–	4
Toxin 1 in 10,000—		
Non-scarlet	1	4
Scarlet	–	5

These findings show that the toxin can be removed from solution by precipitation with alcohol, and also that the loss in toxin during the process of precipitation is probably only slight. A point of considerable interest, to which we will refer in another report, consisted in the fact that, of the scarlet fever cases giving a positive reaction, one was a case which relapsed on the twenty-eighth day of illness, one had myocarditis with multiple abscesses, and two had profuse nasal discharge.

Experiment II.

The same condensation water toxin as that used in Experiment I. was precipitated with four volumes of alcohol. After removal of this first precipitate the filtrate was re-precipitated by adding four more volumes of alcohol. Each precipitate was then made up in carbol saline to the original volume of the toxin and dilutions of 1 in 2000 were used for skin tests. The results were as follows:—

	Positive.	Negative.
Four-volume alcohol precipitate—		
Non-scarlet	2	1
Scarlet	–	4
Second alcohol precipitate—		
Non-scarlet	–	3
Scarlet	–	7

This experiment shows that the first precipitate contains toxin and that the second precipitate either contains no toxin or toxin in insufficient amounts to differentiate between scarlet and non-scarlet cases when used in the dilution indicated.

Experiment III.

A condensation water toxin was tested on a selected series of cases in two separate dilutions with the following results:—

	Positive.	Negative.
Toxin 1 in 2000—		
Non-scarlet	5	–
Scarlet	3	3
Toxin 1 in 4000—		
Non-scarlet	4	–
Scarlet	–	3

Two volumes of alcohol added to this toxin gave a heavy precipitate which was removed, the filtrate being re-precipitated with two more volumes of alcohol. The first and the second precipitates so obtained were dissolved in carbol saline and made up to the volume of the original toxin. Each, diluted 1 in 2000, was then tested on selected cases, the results being:—

	Positive.	Negative.
Two-volume alcohol precipitate—		
Non-scarlet	7	2
Scarlet	–	6
Second alcohol precipitate—		
Non-scarlet	2	2
Scarlet	–	5

These findings show that toxin is present in both precipitates. Further experience of this method has shown that more than half of the available toxin comes down with two volumes of alcohol, and that considerably less than half comes down with further addition of alcohol to four volumes. The two-volume alcohol precipitate is bulky, does not dissolve readily in carbol saline after drying, and shows a considerable amount of insoluble material. On the other hand, the second precipitate taken after removal of the first dissolves very readily after drying and is easy to manipulate in concentrated solutions.

The actual amount of dried toxin which will give good differentiation of scarlet from non-scarlet cases varies with the character of the precipitate. Solutions of 2 to 5 mg. per 1000 c.cm. of carbol saline in the case of the two-volume alcohol precipitates and of the four-volume alcohol precipitates are sufficient for this differentiation, while solutions of 0·2 to 0·5 of a milligramme of the secondary precipitates in 1000 c.cm. of carbol saline produce a like result. The amount of dried toxin that is sufficient for a skin test dose consisting of 0·2 or 0·1 c.cm. of these solutions is therefore represented by 1/5000th and 1/10,000th of the figures we have quoted.

THE DICK TEST IN SCARLET FEVER.

BY C. C. OKELL, *M.C.*, M.B., M.R.C.P. LOND.,

AND

H. J. PARISH, M.D., M.R.C.P. EDIN.

(*From the Wellcome Physiological Research Laboratories.*)

THE small number of observations on the Dick test so far published in Europe encourages us to bring forward the following results. In July last, Okell and Baxter[1] reported the results of a number of tests. Ker, McCartney and McGarrity[2] (1925) have reported a further series. The present communication describes a further series of tests done on scarlet fever patients and on normal individuals.

The Toxin.

The toxin used in all these tests was prepared by us from a strain of streptococcus kindly sent to us by Dr. Dochez. It consisted of a filtrate of a 16-hour-old culture of the streptococcus in Douglas's[3] trypsin digest medium as modified by Hartley[4] and subsequently by Watson and Wallace.[5] An intradermal injection of 0·2 c.cm. of a 1/6000 dilution of the toxin was found to give a well-marked reaction 20 to 70 mm. in diameter in susceptible persons, the average positive reaction being about 20 × 30 mm. Dick toxin is much more heat stable than diphtheria toxin, and is practically unaffected by heating to 75° C. for ten minutes, a procedure which always inactivates dilutions of diphtheria toxin. The method employed for the inactivation of the toxin for the control inoculation is heating to 96° C. for 45 minutes. The constituent responsible for the pseudo reaction seems to be very little affected by this treatment. The toxin keeps for at least two weeks in the diluted state, and phenol (e.g., 0·4 per cent.) may be used as a preservative in the dilutions. Dick toxin, unlike diphtheria toxin, does not appear to produce tissue necrosis. Dick and Dick[6] and others report that many reacting doses can be given without causing any permanent tissue damage. In the dilutions employed in the test it appears to have a vaso-dilator effect on the capillaries. We have prepared toxins not only from Dochez's strain but from strains sent us by Dr. Dick of Chicago and Dr. W. H. Park of New York, as well as from two strains isolated in London by ourselves. All these toxigenic strains appeared to fall into one serological group by absorption tests, and produced toxins apparently identical in properties with that made from Dr. Dochez's strain. They were all neutralised by the serum of people who had recovered from scarlet fever and by the serum of Dick-negative individuals.

No animal other than man has been found to give satisfactory titrations of the toxin. The pig, guinea-pig, rat, mouse, cat, hen and rabbit are practically insusceptible. A toxin which when diluted 1/6000 and injected into susceptible human beings will give a well-marked specific reaction, fails to produce unequivocal reactions in these animals, even in the undiluted state. The monkey (*Macacus rhesus*) was also found insusceptible to the toxin. Kirkbride and Wheeler[7] (1924) have reported that the goat is susceptible to the toxin. We have found it difficult to decide how far the reactions in goats are to be ascribed to the specific scarlet fever toxin. Control fluids such as diluted broth, diluted serum, and heated toxin give rise to quite definite reactions, while the toxin reaction can be partially but not completely neutralised by convalescent serum. The interpretation of results is therefore difficult.

Antitoxin.—We have used toxin for the immunisation of two horses, and the serum obtained was found not only to neutralise an intradermic dose of the toxin in human beings but also, even when considerably diluted, to give rise to the typical Schultz-Charlton[8] blanching of the rash of scarlet fever patients. The therapeutic efficacy of this serum in the treatment of scarlet fever is at present being tested.

Technique of the Dick Reaction.

The technique of the injections is practically the same as that employed for the Schick test.

The skin in front of the forearms is carefully cleansed with spirit; 0·2 c.cm. of a suitably diluted toxin is injected intradermically into one arm, and 0·2 c.cm. of a similar dilution which has previously been heated to 96° C. for 45 minutes into the other.

Reading the Reactions.—Reactions are divided, as in the Schick test, into positive, pseudo-and-positive, negative, and pseudo-and-negative.

Positive Reaction.—The positive reaction develops in from six to 12 hours as a bright red flush with average dimensions of 20 by 30 mm. It has usually reached its maximum in 24 hours, and then rapidly fades away, so that it is usually almost invisible by the seventy-second hour after injection. The reaction thus develops much more quickly than the Schick reaction and fades away more quickly.

In the *pseudo-and-positive, or "combined" reaction*, there is a reaction on both arms, but that on the toxin arm is definitely greater than that on the control.

In the *negative reaction* there is no significant reaction on either arm.

In the *pseudo-and-negative reaction* the reactions, which may vary in size in different individuals, are approximately equal on both arms. The pseudo reaction, as in the Schick test, may remain for several days, and indeed may outlast the positive element of the reaction, a sequence never met with in the Schick test.

In the following series of tests we have also described a *partial positive* reaction by which we mean a small positive reaction a quarter to a half as large as the usual positive reaction, suggesting that a certain amount of the toxin has been neutralised. The significance of this type of reaction in terms of immunity is not yet clear, but as it is more common in those who have had scarlet fever than in those who have not, it possibly indicates that the patient is not susceptible to the disease.

Normal Group.

The normal group consisted of 100 medical students whom we obtained as volunteers through the kindness of Sir Frederick Andrewes. Ninety-five of these were available for reading at the end of 24 hours, the best time in our opinion for reading the tests. (Table I.) The positive rate, 74 per cent. in this group is high. The Schick-positive rate we found in a similar group of medical students was 65 per cent. Twenty of the students had a previous history of scarlet fever, and of these 65 per cent. were read as positive and 35 per cent. as negative. In several of these the history of scarlet fever appeared somewhat indefinite. Seventy-five had a negative history of scarlet fever, and in this group there were 76 per cent. positive and 24 per cent. negative. The percentage of negative reactions is comparable to that obtained with the Schick test in similar individuals who gave no history of diphtheria.

Explanation of signs in Tables. + = Positive. +* = pseudo-and-positive. p+ = Partial positive. p+* = Pseudo-and-partial positive. – = Negative. –* = Pseudo-and-negative. (?) = A reaction difficult to interpret.

In this series we noted the size of the reaction in relation to the history of scarlet fever. From previous observations on young children the opinion had been formed that the standard reaction with the test dose of toxin, in a completely non-immune individual, should be about 30 × 20 mm. Amongst the 70 students with postive reactions we found 36 in whom larger reactions developed, and in three the reactions measured upwards of 70 mm. in one axis. In all cases the area of redness rapidly disappeared. There were no definite pseudo reactions among the 36 individuals who had reactions larger than the normal. The size of the positive reaction appeared to have no relation to the history of scarlet fever. In a few cases only was the reaction greater in area at the end of 48 hours than at the end of 24 hours, and in no case did we read a reaction as definitely negative at the end of 24 hours but as positive at the end of 48 hours. In the whole series of normal individuals pseudo reactions were uncommon. Only one pseudo-and-partial-positive, and five pseudo-and-negative reactions occurred.

Convalescent Group.

The second group of individuals tested consisted of 120 cases of notified scarlet fever from the second to the twelfth week of convalescence. Table II. gives the results of the tests in relation to the period of convalescence.

TABLE II.—*Analysis of Results of Dick Tests in Relation to Period of Convalescence (120 Cases).*

The net results of the tests on scarlet fever convalescents from the second week of convalescence onwards were as follows: Positive group 18 per cent., negative group 82 per cent., the partially positive group amounted to 7·5 per cent. Table III. gives a further analysis of the positive group.

TABLE III.—*Further Analysis of Positive Group in Table II. in Relation to Clinical Diagnosis of Scarlet Fever (22 Cases).*

Definite ..	14	+ 5 +* 1 p+ 5 p+* 3	Doubtful	5	+ 4 p+ 1
			Very doubtful	3	+ 3

Of the 22 read in the positive group 14 had a very definite clinical history of scarlet fever and the remainder were considered from their history and continuous observation during their convalescence to be of "doubtful" character. Of the 14 with a definite history of scarlet fever six only gave strongly positive reactions, one of these being a strong positive and pseudo reaction. The remaining eight gave partial positive reactions. In the case of the six strongly positive cases, the intervals after the alleged onset of the disease were 4, 5, 5, 6, 6, and 7 weeks respectively. One of the strongly positive patients with a history of a very definite attack developed a typical attack of scarlet fever the day after the test had been read. This case illustrates the possible value of the test in investigating the confused subject of relapses in scarlet fever.

As it is generally admitted that the diagnosis of scarlet fever is much more difficult in very young children, an analysis of the reactions was made in reference to age-groups. The numbers of the children under four years old were too small to enable us to draw any definite conclusion from them, but there was some indication that positive reactions were relatively more common in this group. Pseudo reactions, either positive or negative, were unexpectedly uncommon in the group of convalescents. From previous work it seemed that pseudo reactions are more common during the more acute stages of the disease.

Hospital Staff Results.—Thirteen members of the medical and nursing staffs of scarlet fever wards were also tested. All but one nurse had spent a considerable time attending scarlet fever cases, and seven had suffered from definite attacks of scarlet fever. This nurse had been in the wards only a fortnight, and was the only one to give a positive reaction. Nine days after the test she developed a typical attack of scarlet fever.

Discussion of Results.

In both groups it will be seen that an individual with a history of scarlet fever does not necessarily give a negative reaction, even though several weeks have elapsed from the onset of the attack. The normal group with a history of scarlet fever had a Dick-positive rate of 65 per cent. and the convalescent group 18 per cent. The Dick-positive rate in the normal group with a scarlet fever history was therefore undoubtedly high. Two explanations of this unexpected finding are suggested. Either the history given by the individual himself was unreliable, or the immunity to the toxin had disappeared with the lapse of time. It seems, however, reasonably certain that the risk of scarlet fever, to those with a definite history of the disease, is small, and on these results the possibility of individuals being Dick-positive, yet insusceptible to the disease, cannot be excluded.

A similar difficulty occurs in interpreting the results in the convalescent group, where there was a Dick-positive rate of 18 per cent. Four explanations of this discrepancy appear possible: (*a*) That the present methods of diagnosis are not wholly satisfactory; (*b*) that patients who have had scarlet fever do not necessarily become immune to the toxin or become so, in some cases, very slowly; (*c*) that strains of scarlet fever streptococcus may produce more than one toxin; (*d*) that the test is not a true indication of susceptibility to scarlet fever.

With regard to (*a*) it is unnecessary to emphasise the difficulties in making a certain diagnosis of scarlet fever, as indeed it must be for all diseases where the specific cause is still uncertain. (*b*) This seems to be a very probable explanation of at least some of the discrepancies since few diseases will invariably produce immunity, or at least sufficient immunity to neutralise a dose of injected toxin. (*c*) Up to the present there appears to be no evidence that there is more than one scarlet fever toxin. (*d*) The results of the tests, both in the large series done in America and the smaller series done in this country by Ker and by ourselves, are in the main uniformly in favour of the test, and it does not appear too sanguine to consider the comparatively small percentage of discrepancies as due to the inevitable ignorance of the occasional factors governing the test.

It is possible that with the further development of knowledge the standpoint will change, and the bacteriological findings become of real value in diagnosis. For the moment the laboratory worker must accept the opinion of the experienced clinician rather than suggest any readjustment of the diagnosis by an appeal to a test which is still in the experimental stage.

Conclusions.

1. Amongst 95 medical students 74 per cent. gave positive response to the Dick test. Amongst 20, who had a history of scarlet fever, 65 per cent. gave a positive reaction; of 75 students who had no history of scarlet fever 24 per cent. were negative to the Dick test.

2. Amongst 120 patients entered in the hospital records as convalescent from scarlet fever, 82 per cent. gave a negative reaction; amongst the 22 (18 per cent.) with a positive reaction there were 6 giving a strongly positive reaction, who were considered to have had a definite attack of scarlet fever.

3. On the whole, our experience of the test agrees with that of Dick, Zingher,[9] [10] and others.

Tests by Other Observers.

1. Dr. E. H. R. Harries, in conjunction with Dr. James Chalmers, made some tests at the City Hospital, Little Bromwich, Birmingham, in 1924, with toxin which we prepared from the Dochez strain. Dr. Harries has allowed us briefly to quote some of these results, which were as follows:—

> Of 11 children suffering from diphtheria, without previous history of scarlet fever, eight gave a positive response to the Dick tests: one a pseudo-and-positive; and two a pseudo-and-negative reaction.
>
> Of nine children tested during convalescence from scarlet fever, all gave a negative response. Another child who had been notified as suffering from scarlet fever but who gave no definite evidence of the disease and was "barrier nursed" throughout, showed a positive reaction.
>
> Some members of the nursing staff were also tested with this toxin. Of 42 nurses so tested, 16 gave a history of scarlet fever. Twenty-eight showed a negative reaction, and nine a pseudo-and-negative, whilst only four gave a positive or slightly positive response, and one a pseudo-and-positive reaction.
>
> Two of the four positive results were obtained in nurses who stated that they had had scarlet fever. Both these attacks were said to have occurred in hospital, and it was therefore possible to investigate them. In both instances the attack was of a very doubtful nature.

It is to be noted that in all the above tests 0·1 c.cm. of the toxin and of control was employed.

Dr. Harries and Dr. Chalmers also, before deciding to use therapeutically horse serum which we had prepared by immunisation with toxin from the Dochez streptococcus, tested the serum for the production of the blanching reaction. They found that the horse sera used, either neat or diluted from 1-10 to 1-100, gave a typical Schultz-Charlton blanching of the rash in every case of scarlet fever tested, but failed to blanch an enema rash, a rash associated with encephalitis, or a toxæmic rash due to constipation. Normal horse sera used for controls failed to produce blanching in any instance.

2. Dr. F. Foord Caiger arranged for the carrying out of some Schultz-Charlton tests by Dr. Ruby Inkster at the South-Western Hospital. Dr. Inkster has very kindly supplied us with a preliminary record of some of her work.

> Serum obtained during convalescence after a typical attack of scarlet fever gave a positive Schultz-Charlton blanching when tested on the rashes of three patients suffering from scarlet fever. Various samples of normal horse sera were tested in 20 instances, but in all cases failed to blanch the rash. Serum from horses we had immunised with toxin made from a strain of the specific streptococcus was tested on the rashes of 43 patients. Serum A, when used either neat or in various dilutions up to 1 in 100, produced blanching in every instance (30 cases); serum B, tested in 13 cases, produced blanching in nine, in dilutions up to 1 in 10. Therapeutic serum which had been used in America, and which we owe to the courtesy of Dr. Dochez, gave positive blanching results in all ten cases tested, the serum being diluted 1 in 5 or 1 in 10, and some therapeutic serum which Dr. W. Park, of New York, very kindly sent us produced blanching in three out of five cases.

The figures are too small to allow of a comparison of the "blanching titre" of the various sera used, but as far as can be judged from this series of tests it would appear that the sera we have prepared possess the specific antitoxin in reasonable concentration.

We owe our thanks to Dr. R. A. O'Brien, Dr. Foord Caiger, Dr. Howell Griffiths, Dr. Harries, and Dr. Ruby Inkster for the help they have given to us in this work.

THE EXPERIMENTAL PRODUCTION OF CANCER

BY ONE APPLICATION OF TAR.

By G. MARSHALL FINDLAY, O.B.E., M.D., Sc.D. Edin.

(From the Laboratories of the Imperial Cancer Research Fund, London.)

Of the many explanations which have been given of the genesis of cancer the only one which, up to the present, has been confirmed by experimental results is the theory of Virchow in regard to the rôle of chronic irritation. All the carcinogenic agents now known—tar, soot, arsenic, X rays, radium, *Spiroptera* or *Tænia crassicollis*—depend on the fact that their continued application gives rise to irritation of a chronic character. Even in the case of tar, it is necessary to continue its application to the skin of a mouse for at least four months before an epithelioma is produced. Nevertheless, despite the importance of the chronicity of the irritation, there is not wanting evidence to suggest that under certain conditions the single application of a carcinogenic agent may give rise to cancer. Evidence in support of this view is partly clinical, partly experimental.

Clinical Records.

Story (1885)[1] cites the case of a carbolic worker who received a splash of crude carbolic on the conjunctival surface of the left lower eyelid. Four months later an epithelioma was removed at operation from the area which had been touched by the carbolic. The diagnosis was confirmed by microscopical examination.

Bang (1923)[2] records the case of a tar worker who while opening the door of a retort was splashed by a bead of hot tar, which fell on the skin just within the left nostril. Sixteen days later an epithelioma the size of a coffee bean was removed at operation from the area which had undergone the trauma.

In both these cases the single application of an irritant was followed by the occurrence of a carcinoma. It is probable that records of similar cases, though by no means common, are to be found in the literature.

There are, of course, many cases where injury to a limb is followed sooner or later by the recognition of a malignant growth, usually a sarcoma, at the site of injury. The difficult question always arises, however, as to whether the trauma has not simply served to draw attention to a previously existing neoplasm. In the two cases here cited this difficulty does not arise. It may, however, be objected that both patients had worked for some years with carcinogenic agents. It is possible, though not probable, that the areas on which the epitheliomata developed may have been subjected to prolonged irritation.

Experimental Results.

To obviate this criticism it was determined to try the effect of a single application of hot tar to the skin of mice. The following experiments were therefore carried out:—

Feb. 29th, 1924: Fifty mice received one application of a chloroform extract of tar heated to a temperature of 70° C. on the depilated skin of the back.

April 11th: Twenty-five mice received one application of the same tar heated to 70° C., the tar being applied to three small areas forming the apices of a triangle on the back of the mice.

Feb. 4th, 1925: Thirteen mice were still alive. Two mice from the first and one from the second series had developed epitheliomata on the skin of the back. The three tumours exhibited continuous growth, and in their naked-eye and microscopic appearances resembled in every way the epitheliomata produced by the long-continued application of tar.

These experimental results serve, therefore, to confirm the clinical cases previously cited by showing that the action of carcinogenic agents on the cell is mediate rather than immediate. By the law of probability it is far more difficult to obtain a given result by a single attempt than by repeated attempts. As, however, our knowledge of the essential cell changes involved in cancer development becomes more advanced it should be possible to produce cancer invariably by a single intervention.

FINANCES OF UNIVERSITY COLLEGE HOSPITAL.—Last year's accounts of this hospital show a deficit of £11,500, which brings the total deficit for the last six years up to £45,000.

ROYAL HALIFAX INFIRMARY.—A new maternity ward at the Halifax Infirmary was opened recently by Princess Mary, Viscountess Lascelles. The ward, named the Linford Moore Kitchenman Maternity Ward, has been erected as the result of a legacy of £5000 by the late Mr. Charles Kitchenman of Halifax, and other donations include £2000 from Mr. Frank Lee, President of the infirmary, and £1000 each from Sir William Bulmer and Sir Harold Mackintosh. The ward will accommodate 20 patients.

Medical Societies.

HARVEIAN SOCIETY OF LONDON.

A MEETING of this Society was held on March 27th, Sir JOHN BROADBENT, the President, being in the chair.

Sir CRISP ENGLISH opened a discussion on

OBSTRUCTION OF THE COLON.

He said that the subject was one which teemed with difficulties and the results of treatment were at present deplorable, having an operative mortality of 30–40 per cent. Excluding, for the purpose of this discussion, intussusception, external herniæ, and intestinal stasis, the remaining cases of obstruction were due in 80 or 90 per cent. of cases to malignant disease, 85 per cent. were on the left side and 50 per cent. in the pelvic colon; 35 per cent. of the cases were acute.

Diagnosis.

The diagnosis must rest on a careful study of early symptoms, which were often so slight that they failed to impress the doctor. There was little hope of improvement until the profession had learned the doctrine of early diagnosis, but to endeavour to teach it to the public would only result in a great increase of neurasthenia. The problem was essentially a suitable one for treatment by modern clinical methods, calling for every type of investigation available. The experienced observer was able to detect a characteristic facial aspect in the patient, or attention might be drawn to the case by the appearance, for the first time, of abdominal discomfort and constipation in elderly subjects. Often there was very little pain, but some localised borborygmi were noticed and a feeling of trickling in the neighbourhood of the growth. But there was no symptomatology of carcinoma of the colon until the onset of some degree of obstruction. The keynote to this was the distension and hardness of the cæcum. Diagnosis and localisation must rest to a large extent on the X ray findings, which should be based on a barium enema, supplemented by a barium meal and observations under the screen as well as photographs. Frequently barium meals and enemata were much too bulky, producing an exaggerated and distorted picture or a confusing mass of shadow. Sometimes an enema would pass right through a carcinoma, and radiological evidence must be taken in conjunction with the clinical signs and symptoms. Gas in the colon would at times serve to show the site of a partial obstruction without the presence of any opaque substance. Sigmoidoscope examination was also helpful.

The present high mortality might be attributed to three factors: (1) Delay, whereby the patient came to operation in a condition of profound toxæmia. (2) Attempting too much; there was often confusion between relief and removal of the cause. In acute cases relief only must be considered and cure postponed. (3) Anæsthetic. As much as possible should be done under local or spinal anæsthesia. A heavy general anæsthetic greatly reduced the patient's chances in an acute case.

The only practicable operation in desperately toxæmic cases was a *blind cæcostomy*, and this was the measure of election in all acute cases unless there were some definite indication for a colotomy. It had the advantages of being rapid and could be done under local anæsthesia with a small incision. It was fatal to allow distended coils of intestine to get outside the abdomen as they could never be replaced. Exploratory laparotomy should only be performed when there was no appreciable distension. If the pulse were more than 140 it was futile to operate at all. Whatever operation was undertaken, it was advisable to do a cæcostomy as a temporary measure in addition. Colotomy was good in suitable cases and Murphy's button often relieved the discomfort of the first few days, being better than a Paul's tube. Appendicostomy was useless, as the drainage was uncertain and ineffectual. Paul's operation still had its advocates, but as it was only suitable for small growths in the pelvic colon it should be replaced by excision.

Discussion.

Mr. T. P. **Legg** doubted whether cæcostomy were always the right treatment; it did not allow for such causes of obstruction as volvulus. He doubted whether it were worth operating at all if the patient were so ill as to need a cæcostomy; where there was a reasonable chance of the patient doing well it was better to open the abdomen and find out what condition was present, either with a view to future operation or to immediate excision or short-circuit. He questioned whether the drainage was as perfect through the cæcostomy as was believed; at subsequent operation the ascending and transverse colon were often found inflamed and distended with liquid fæces. The best anæsthetic was the lumbar. Tuberculosis of the ileo-cæcal valve simulated carcinoma very closely and might cause obstruction. In a case under his care the lump felt before operation soon disappeared after the obstruction had been relieved, but the patient subsequently developed phthisis; he asked whether it were a fact that individuals with tuberculosis of the ileo-cæcal valve were particularly liable to virulent phthisis. He also asked whether the annular carcinomata were really as innocent as was stated; if so, the best treatment would seem to be simple drainage. Another type of case to which he desired to call attention was that of pure spasm, which often occurred in the region of the splenic flexure. There were no further symptoms after the obstruction had been relieved by colostomy.

Mr. **Montague Smith** spoke of the difficulty of diagnosis from the point of view of the general practitioner, and quoted two cases which had come under his care. One was a man of 66 who had a hard tumour in the cæcum which increased in size while under observation. A diagnosis of malignant growth, possibly retroperitoneal, was made, but the passage of a catheter resulted in the withdrawal of large quantities of urine and the collapse of the tumour. In another case there was epigastric swelling, but the physician called in was of the opinion that it was not carcinomatous and ordered horse-riding and massage. Shortly afterwards the patient vomited pints of foul fæculent material, the massage having burst a growth connecting transverse colon and stomach. Mr. Smith had found paraffin a disappointing remedy, while the administration of small doses of calomel over long periods, in cases where there was obstruction, was dangerous, as it might be retained and produce mercurial poisoning.

Mr. G. A. **Ewart** spoke of the difficulty of diagnosing between obstruction and general peritonitis in elderly people, who did not show the characteristic constitutional signs of pus in the abdomen. He did not believe in blind cæcostomy. No case should be left so long as to be unfit for exploration. He did not approve of attempting any anastomotic procedure at the time of operating for acute obstruction; every case should be allowed to recover from the toxæmia, and the stitching, when done, should be good enough to be relied upon without the insertion of a tube, which invariably resulted in a fæcal fistula. He believed that every case of volvulus sooner or later required resection of the sigmoid. If cæcostomy were done in a case of acute obstruction at least three weeks must be allowed to elapse before any further operation.

Sir John **Broadbent** quoted three cases illustrating the extraordinarily protean character of this condition. One case was treated as rheumatoid arthritis and there was never any evidence of obstruction; the patient died of carcinomatosis of the peritoneum. The second was a case of heart disease; on examination some distension of the colon and visible peristalsis led to a diagnosis of carcinoma of the sigmoid. X ray examination revealed no obstruction, but manifested a caseating tuberculous kidney. At operation a large infiltrating growth of the sigmoid was found. The third case was diagnosed as appendicitis with concretions; at operation the "concretions" proved to be malignant glands secondary to a large growth in the cæcum. The patient completely recovered after a short-circuit had been performed, but died three and a half years later from secondaries in the ribs and other bones.

Mr. **Ivor Back** spoke of that form of *diverticulitis* which follows from chronic septic and fibrotic invasion of the colon producing a solid sausage-shaped mass resembling a carcinoma. The condition was comparatively common in proportion to other diseases of the colon. The differential diagnosis between the two conditions was extremely difficult, even at operation. In his experience there was a very frequent history of some urinary involvement in diverticulitis, even fæcal fistulæ, and in this condition the characteristic string-like constriction of the carcinomatous bowel was seldom found. He asked what was the correct procedure when the diagnosis of diverticulitis had been made; in the Mayo Clinic the mortality associated with excision and anastomosis was 18 per cent., while that of colotomy was nil; moreover, the tumours very often disappeared completely after colotomy. With regard to the blind cæcostomy, cases must be divided. Where a laparotomy could be borne by the patient it was better to do it and obtain as much information as possible, but the operation of blind cæcostomy was justified in cases with a pulse of 120 and much distension. Anastomosis in a state of toxæmia was useless as the streptococci behind the obstruction destroyed the ligatures, producing peritonitis.

Dr. H. C. H. **Ball** agreed that diverticulitis was commoner than was supposed; it was to be diagnosed by the presence of other diverticula and by the presence of spasm in association with obstruction.

Mr. G. **de Bec Turtle** pointed out that obstruction of the colon might be due to dilatation at the extremes of life without any pathological changes to account for it. Spasm occurred chiefly in middle life and in females and those who take purgatives constantly. Such cases were very difficult and could only be diagnosed by careful radiography or by catching the colon in a condition of spasm. Often they were set up by some irritation low down in the bowel producing idiopathic dilatation and so leading to a pseudo-obstruction.

Dr. J. **Blomfield** said that if a patient could stand an operation at all he could stand a general anæsthetic if properly given. The great factor was the length of time taken. The difficulty of returning coils of distended intestine to the abdominal cavity involved very complete relaxation; surgeons were apt to forget that a stimulus might be so violent that no amount of anæsthetic would prevent its getting through.

Dr. J. **Morton** said that what first should raise the suspicion of the practitioner was an early loss of appetite with changes in the secretion of the mouth, such as dry-coated tongue. It seemed that when the cæcum got into difficulties the stomach always tried to do as little work as possible. Secondly, the alteration of the patient's reaction to aperients; either the customary pill failed to act or else upset him far more than before. There might also be loss of flesh, hæmorrhage ascribed to piles, also the borborygmi and trickling as previously described. Paraffin in his experience was dangerous in that it might lull to a false security by causing total disappearance of symptoms until the sudden onset of acute obstruction.

Dr. G. **Orme** emphasised the difficulties of diagnosis; a very large proportion of the cases operated on for acute obstruction had had no previous symptoms at all. He also had found that patients noticed an inefficiency in their usual aperient, while a stronger dose of it was liable to lead to griping pains in the lower abdomen which had never before been experienced.

Reply.

Sir **CRISP ENGLISH**, in replying, said that the great need was to find some way of reducing the mortality under present methods. It was to this end that he had adopted cæcostomy. Volvulus occurred in 1·5 per cent. of cases only, and if the 1·5 per cent. were catered for by exploration there would be a loss of some 10 or 20 per cent. of other types of case. He thought that anastomoses should be drained although it did produce fæcal fistula; better a live patient with a fistula than a dead one without.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

GONOCOCCAL AND SYPHILITIC AFFECTIONS OF THE EYE.

A MEETING of this Society was held on March 27th, Colonel L. W. **HARRISON**, the President, being in the chair. The evening was devoted to a discussion on the above subject.

Syphilitic Eye Conditions.

Mr. N. **BISHOP HARMAN** dealt with the eye conditions due to syphilis, and, owing to the varied extent of these eye affections due to that disease, he said he would take, as his main thesis, syphilis as a cause of blindness, blindness being the bill of mortality of that important organ. He would be able to show, he said, that syphilis was accountable for more blindness than was any other single infection or degeneration of the eyes. The material on which this contribution was based came from three sources: (1) A well-known home for blind babies; (2) several schools for the blind established by the London County Council; and (3) cases from his private practice, a total of well over 5000.

Mr. Harman had examined 200 blind infants, mostly at about a year old. When admitted to the home they remained there until their fifth year, and were then transferred to other blind schools. In these infants there were three causes of blindness: Surface inflammations, inflammations within the eyeball, and congenital defects. More than half these cases belonged to the first group, ophthalmia neonatorum being the chief contributor—49 per cent. of the cases; purulent conjunctivitis due to acute infectious diseases yielding 8 per cent. In the second group the prime cause seemed to be congenital syphilis. The third group embraced congenital defects of the eyes, mostly due to lack of development or to a pathological arrest of development, some of them syphilitic. At least 60 per cent. of these babies owed their blindness to parental venereal disease (50 per cent. from gonorrhœa, 10 per cent. from syphilis).

Blind School-Children.

The school-children examined by Mr. Harman numbered 3300, and he had classified them for two special purposes, with an interval of seven years between—namely, for submission to the Royal Commission on Venereal Diseases, and to the Departmental Committee on the Causes and Prevention of Blindness. More than half the infants were blinded by ophthalmia neonatorum. With regard to the surface inflammations, 699 of the children were blinded in this way. Total blindness was caused by ophthalmia neonatorum in 369, purulent conjunctivitis of later years in 90, and phlyctenular keratitis in 242. Children blinded by inflammation in the front half of the eye numbered 413, chiefly due to interstitial keratitis, an effect of congenital syphilis. Iritis and irido-cyclitis accounted for 14, syphilis being responsible for all but two of them. Of 242 cases of disseminated choroiditis, 210 were certainly attributable to congenital syphilis. Summarised, the figures showed that venereal disease in parents accounted for more than half the blindness found amongst school-children—i.e., children between 7 and 16 years of age.

Patients of All Ages.

Dealing next with the third source of his material, private practice, he said that of 5000 cases he had examined, of all ages, 925 were blind in one eye or in both, while 603 were partly blind on one or both sides. Ophthalmia neonatorum accounted in this group for only 17, and only one adult had gonorrhœal ophthalmia. At all ages, including the young and the very old, blindness from venereal disease was about 14 per cent. of the whole—i.e., 2·5 per cent. from gonorrhœa and the rest from syphilis. Viewing the matter from another angle, that of the results of measures taken to reduce blindness and other sequelæ of venereal disease, he gave the number of blind children per 100,000 school-children in 1907 to 1913, and again in the years 1914 to 1920. In the former period the percentage of ophthalmia neonatorum was 18·3, that of congenital syphilis 46·8. The comparative figures for the later years were 12·5 and 40·2 respectively, showing 6 per cent. reduction in each class.

He next dealt with the clinical signs of syphilis, remarking that in school work the diagnosis of congenital syphilis must rest largely on associated symptoms. In 190 cases of interstitial keratitis due to congenital syphilis he found Hutchinsonian teeth were present in 129, the characteristic physiognomy in 73, iritis in 77, disseminated choroiditis in 30, and 72 had a bad family history. Of 51 cases with disseminated choroiditis, 22 became insane, 18 were mentally deficient, 2 were microcephalic idiots, and 9 epileptic.

Mr. Harman proceeded to deal with the serious effects of syphilis on the results of pregnancy, and his remarks led up to his exhibition of the following instructive table:—

—	Healthy children.	Mis-carriages.	Still-born.	Infant deaths.	Diseased with syphilis.
Syphilitic ..	399	92	80	229	210
"Average" ..	791·7	73·8	20·5	113·8	—

Syphilitic mothers had 17 per cent. more pregnancies than did "average" mothers, probably because of the frequency of miscarriages among them.

In conclusion, he expressed his appreciation of the earnest work which was now being carried on in the V.D. clinics of the country, and said that eye and other specialists looked hopefully to the workers in those centres for a substantial reduction of these tragedies of life.

Gonorrhœal Affections of the Eye.

This part of the subject was dealt with by Mr. **CYRIL HUDSON**. He considered the infections under the headings of exogenous and endogenous, and said that gonococcal infection of the conjunctiva might occur not only before birth, but before rupture of the membranes took place. The nurses controlled by the Central Midwives Board were not allowed to use more elaborate measures for preventing ophthalmia neonatorum than wiping the eyes of the infant free from all moisture as soon as the head was born. Credé, by wiping the eyes with clean linen and ordinary water, and then allowing a drop of 2 per cent. silver nitrate to fall off a glass rod into the eye, reduced his cases of this condition from 10 per cent. to under 0·5 per cent. But the time of greatest danger to the eyes of these infants was immediately after rather than during birth, as there was then risk of infection of the eyes from the baby's hands before they were washed, and from the bath water entering the eyes, and precautions must be taken accordingly.

Corneal complications were specially likely to occur in weakly babies, congenital syphilitics, and those born prematurely. The lesions of the cornea ranged from infiltration without loss of substance to ulceration leading to destruction of almost the whole of the cornea. The disease might be complicated by arthritis, endocarditis, or septicæmia. The blindness following corneal ulceration might lead to disorganisation of the eye or secondary glaucoma, but the latter might sometimes be obviated by a timely operation. Care should be taken when examining cases in which the lids were glued together by purulent ophthalmia, as the reservoir of pus might be injected into the eye of the observer when he separated the lids. To prevent this, a lotion should first be applied, on cotton-wool, and a further reason for the use of gentleness was to avoid rupture of a delicate cornea.

With regard to *treatment*, Mr. Hudson said bad results were sometimes due to over-treatment in the form of the application of strong irritating solutions, such as perchloride of mercury. If the latter were used, its strength should not exceed 1 in 20,000. Some text-books advised the use of lotions stronger than he thought desirable. He considered that Mr. Mayou's method of treatment was very good. It consisted of 1 in 6 of eusol for washing away the conjunctival discharge, followed by the instillation of flavine 1 in 1500 in castor oil. This could be renewed every three or four hours. Mayou did not find ordinary or detoxicated vaccines of any value in these cases. He thought both the mother and father of these children should be treated. If treatment of the child were carried out in the home the injunctions in regard to precautions against spread of the disease could not be too emphatic. In adults gonorrhœal conjunctivitis was comparatively rare. Livingstone had reported remarkable success from the subcutaneous injection of colloid manganese, and good results were said to have followed milk injections, while Allison's success with typhoid vaccine in these cases was quite marked.

Endogenous gonorrhœal inflammations of the eyes were seen as conjunctivitis and irido-cyclitis. The latter might occur within a fortnight of the initial gonorrhœal infection. Often it was bilateral. In gonorrhœal iritis he had frequently seen blood in the anterior chamber. In doubtful cases it was not wise, in making a diagnosis, to use atropine, as it might precipitate a threatening glaucoma. In these doubtful cases it was better to instil a little cocaine ; 2 per cent. cocaine and 2 per cent. atropine ointment placed between the lids was useful for the relief of pain.

Dr. T. H. C. **BENIANS** spoke from the pathologist's point of view. He said that though the bacteriological diagnosis of gonococcal infections of the eye was not difficult, neither was it very certain, especially in chronic cases. In doubtful cases a positive result could be obtained from an investigation of the vesiculæ seminales. Dealing with superficial infections of the eye with the gonococcus, he said it was an unstable coccus ; it did not itself excrete a toxin, but when it was broken down it produced a protoplasmic substance which was deleterious and disharmonious with the human being. Yet it rapidly took root in certain parts of the body and caused virulent symptoms where other organisms would not secure a footing. The seats of trouble were usually those where there was a comparative stasis ; and within a few hours of the toxin having touched unprotected nerve-endings there was a violent reaction in the blood-vessels of the part. Instead, therefore, of being obsessed by the thought that a coccus was present, the effort of the doctor should be to alter the nidus in which the gonococcus was flourishing to one in which it would be far from happy.

A discussion ensued, in which the **PRESIDENT**, Dr. D. **NABARRO**, Dr. **FOWLER WARD**, Dr. **MARGARET RORKE**, Dr. **MILLS**, and Dr. **SHARPE** took part. Mr. **BISHOP HARMAN**, Mr. **HUDSON**, and Dr. **BENIANS** briefly replied.

Reviews and Notices of Books.

MODERN OPERATIVE SURGERY.

Edited by H. W. CARSON, F.R.C.S. London : Cassell and Co. 1924. In two vols. Pp. 1568. £3 3s.

THE field of surgery has become so vast, and the operations which are now included in its scope are so many and so varied, that it is impossible for one man to make himself master of the whole subject. In these volumes a successful attempt has been made to grapple with the problem of supplying minutely detailed descriptions of all operations by those accustomed to perform them, and the result is a work on operative surgery on entirely new lines. It is divided up into a large number of articles for each of which an acknowledged expert in that particular subject is responsible, and though each of the authors sees surgery from his own point of view, a most striking feature of the book is the unity of the whole. The stern hand of the editor must have exercised the most rigid compression, for nothing else could have kept these volumes down to a reasonable size, but he has used his powers with great judgment. Out-of-date methods have been ruthlessly rejected, whatever their historic interest, but a full description is given of all those methods which would be accepted as sound to-day by experienced surgeons.

All the articles are good ; some are outstanding. For example, in the first volume considerable space is devoted to operations on the locomotory system, and nothing could better show the breadth of outlook which pervades the book than the first article of this series, written by Sir Henry Gauvain, on surgical tuberculosis. The inclusion of sunlight and bathing as methods of treatment in a work on operative surgery is unusual, but is certainly justifiable. The methods of orthopædic surgery are dealt with in a series of articles by Mr. R. C. Elmslie and Mr. Jenner Verrall. The section on amputations is especially valuable, since in a few pages is compressed all that the student need know and, indeed, all that most surgeons will ever require to derive from a book. The experiences of the war have largely altered our views on amputations, but it is still true that no class of operation requires a more perfect and exact technique. Mr. Hey Groves contributes an important paper on fracture operations. There is no more difficult branch of surgery than that which concerns the bones, and his clear descriptions are valuable. In his article on the nerves Mr. H. Platt has gathered into a short space all that the war taught us on this difficult subject. Mr. Richard Warren, in his article on the thorax, covers with extraordinary brevity a subject the importance and possibilities of which are only now being realised. Mr. A. J. Walton deals adequately with operations on the spinal cord and also contributes an important article on the surgery of the thyroid gland. His description of technique will be appreciated and his cautions as to the preparation and management of these cases should be carefully studied. Mr. Sampson Handley contributes two remarkable articles on the treatment of malignant disease of the breast. We have read no sounder exposition of the modern views of cancer, the foundations of which rest in many places on his own researches. Mr. Grey Turner's article on the liver and biliary system is

(*Continued from previous column.*)

ERRATUM.—In THE LANCET of March 28th, p. 661, the classification of radiation therapy as adopted by Dr. Douglas Webster should be read as follows: Superficial (100,000 volts and under), medium (100–150,000 volts), and really deep therapy (150,000 volts and over). Dr. Webster further stated that "cases of breast carcinoma were best treated prophylactically by medium deep therapy, with 3 mm. of aluminium *or* 0·2 zinc," not "*and*" as reported.

exhaustive. The procedures which the surgeon may be called upon to perform in this difficult region are complicated, but admirable illustrations illuminate the section, and even a student should have no difficulty in following the descriptions. Operations on the skull and brain are dealt with by Mr. Bathe Rawling with sound common sense. Particularly good are the pages he devotes to gunshot wounds of the skull. The actual technique of the operations he describes could, as he says, be carried out by any experienced surgeon, though we hardly agree that they can safely be undertaken by a surgeon who has not special experience of such work. Indeed, so difficult are the decisions which have to be made at the operating table that some hold the view that removal of a cerebral tumour should only be attempted in the presence of at least two first-class opinions in consultation at the actual operation. Mr. Gillies deals with plastic surgery, supplying an inspiring epitome of the subject from the most modern standpoint. The article teems with new and practical ideas, and the author might in some places, we think, justly have claimed personal credit to which he lays no claim.

To Mr. Carson, the editor, falls the task of dealing with abdominal operations, and he performs it in a series of admirable articles. The task of selecting a series of representative operations must have presented great difficulties. The successful compression of these into so small a space without the loss of any important detail is a great feat. In the article on gastric ulcers the orthodox practice of the present day is explained, described, and illustrated with great clearness. It is refreshing to read an article on this subject in which the author does not lose himself in a maze of alternative methods, but describes a selected group of operations with the detail they deserve. Sir John Thomson-Walker and Mr. John Everidge are responsible for the articles on genito-urinary surgery. Many new methods are described, and the sections are well up to the high standard of the book.

A series of articles on special subjects forms a very valuable addition to the work, being a recognition that many surgeons have to undertake a much wider range of surgery than specialists in great centres are called upon to consider. These sections are sufficiently advanced to appeal to the specialist, while clear enough to help the general surgeon called on to do an operation well outside his usual range. The short space devoted to anæsthetics is taken up by Dr. J. Blomfield with a sound account of the methods of general anæsthesia, full of valuable hints. Only two-thirds of a page is devoted to local anæsthesia; it is likely that this space will have to be largely increased in a future edition, for infiltration anæsthesia will surely hold an important place in the future of surgery.

This work may be taken as representative of the established practice of English surgery at the present day. Its production is a really fine achievement.

CLINICAL RESEARCHES IN ACUTE ABDOMINAL DISEASE.

By ZACHARY COPE, B.A., M.D., M.S. Lond., F.R.C.S. Eng., Senior Surgeon to Out-patients, St. Mary's Hospital, Paddington; Senior Surgeon to the Bolingbroke Hospital, Wandsworth Common. London: Oxford University Press. 1925. Pp. 148. 12*s.* 6*d.*

IN this volume the author has collected together a series of articles which he has contributed from time to time to various journals. They all centre round his own clinical observations, and it is a feature of these observations that they have been made without instrumental or laboratory aid of any kind. The book is, in fact, a protest against the undue stress apt to be laid at the present time on complicated methods of laboratory technique, and a plea for a return to the simple and direct observations upon which our fathers had to depend for diagnosis, and in which they developed such amazing skill. Practically every chapter discusses from some point of view the interpretation of pain as a symptom of disease, and none will dispute the clinical importance of this aspect of medicine. In addition to collating the observations of Head, Sherren, and many others, Mr. Cope describes several valuable tests of his own invention, such as the obturator and femoral tests, which have now passed into general use. Numerous descriptions of cases illustrate his ideas, and the sequence which he cites in order to establish his theory regarding phrenic shoulder pains is of real interest. The book is full of suggestive ideas, and not the least part of its value lies in its appeal to the clinician to use his hands and eyes.

ENDOCRINOLOGY.

Goiter. Nonsurgical Types and Treatment. By ISRAEL BRAM, M.D. New York: The Macmillan Company. 1924. Pp. 479. 31*s.* 6*d.*

Les maladies des glandes endocrines. By Prof. KNUD H. KRABBE. With a preface by Dr. STEPHEN-CHAUVET. Paris: Libraire Le François. 1925. Pp. 94. Fr.10.

THE American author, in a book entitled "Goiter," has some definite object in view other than to assemble all the known facts on the thyroid gland and its disorders. The subtitle of Dr. Bram's book gives the clue to what this object is, and the book consists for the most part of an elaborate plea against surgical interference in cases of exophthalmic goitre. An attempt is made to classify these non-surgical goitres on a rough pathological basis as the unencapsulated varieties of thyroid swellings, but the real classification adopted by the author is what he calls a therapeutic one. If an enlargement of the thyroid gland and the consequent disorder of the human economy can be cured by correct non-surgical procedures, then that type of enlargement is a "nonsurgical" one. Dr. Bram will only allow the surgeon to interfere in Graves's disease if there are marked pressure signs, if there are malignant changes in the gland, or if any septic focus requires eradication. His description of the treatment and general management occupies nearly half the book, and while there is no doubt that exophthalmic goitre will frequently yield to the strict régime, the carefully selected diet, the medicinal, local, and psycho-therapeutic treatment as here described, the cure may be tedious and uncertain.

In Prof. Krabbe's book on the internal secretions this very point is emphasised, for he holds that surgical treatment of exophthalmic goitre is definitely indicated "if the patient cannot afford the cost of a long treatment which necessitates cessation of his occupation." Prof. Krabbe's book has the great merit, somewhat uncommon in books on this subject, of being short. In less than 100 pages the whole of what is now termed "endocrinology" is rapidly surveyed. Numerous excellent photographs of patients illustrate the classical types of disorders of the internal secretions, and each ductless gland is dealt with in turn with reference to pathology, symptomatology, and treatment. Of the two authors Prof. Krabbe had probably the more difficult task; his greater success is therefore the more creditable.

THE BLOOD.

A Guide to its Examination and to the Diagnosis and Treatment of its Diseases. Third edition. By G. LOVELL GULLAND, C.M.G., M.D., F.R.C.P.E., Professor of Medicine and Clinical Medicine in the University of Edinburgh; and ALEXANDER GOODALL, Assistant Physician in the Royal Infirmary, Edinburgh. Edinburgh: W. Green and Son, Ltd. 1925. Pp. 424. 25*s.*

FOR the past 12 years this work has occupied a proud position in this country as a standard text-book upon diseases of the blood, and there is every reason to believe that it will contimue so to do. The present edition follows closely upon the lines of the second, There may even be complaints that sometimes it follows almost too closely. At any rate, those hæmatologists who are always searching after some new thing—which sometimes means an old thing under a new name—will not find much to their taste in its pages. For the student, the practitioner of medicine, and the laboratory worker the book remains a mine of valuable information. The conservative attitude of the authors is consistent throughout the book; in the preface they protest against "the excess of differentiative nomenclature in which some writers have indulged," while in the index search is vain for the polysyllabic hybrids which burden the Folia Hæmatologica. For the most part the matter has been brought thoroughly up to date, though in some places the additions are rather sketchy, and in others a fuller statement of views in opposition to those held by the authors would have added to the value of the work. For example, that in the leukæmias the white cells found outside the bone marrow reach the sites at which they are to be found post mortem by a process of "infiltration," is not so evident to everyone as it is to Prof. Gulland and Dr. Goodall: the evidence is equally good, perhaps even better, for a local production. A study of recent American literature might further have shaken the faith of the authors in another article of their creed, namely, that the largest leucocyte—that cell having no generally accepted name, but described by Nägeli as the "monocyte"—is merely an overgrown lymphocyte. Of the numerous suggestions that have been made as to the nature of this particular cell, this seems to us one of the least happy.

In the clinical sections there can be no question as to the value of the sober and conservative nature of the authors' outlook. Yet it is depressing to mark how little advance in the treatment of any of the blood conditions has been made since the appearance of the last edition.

The Meaning of Meaning.

By C. K. Ogden and I. A. Richards. With an Introduction by Prof. Postgate, and Supplementary Essays by Bronislaw Malinowski, Ph.D., D.Sc., and F. G. Crookshank, M.D., F.R.C.P. International Library of Psychology, Philosophy, and Scientific Method. London: Kegan Paul, Trench, Trübner and Co., Ltd. Pp. 544. 12*s.* 6*d.*

For a good many years now the study of the nature and foundations of knowledge and of the processes involved in thought and the expression of thought has ceased to play any necessary part in the education of medical students. This is the more to be regretted since, at the present day, no subject more urgently occupies the attention of men of science and of philosophers than does that of the relations on the one hand between the *problems* of philosophy and those of science, and, on the other, of those between the *methods* of philosophy and those of science. Philosophers have to consider the processes and nature of the human intellect: men of science, in these latter days, must consider how far the subjective conditions of sense experience, of thought, and of the expression of thought, qualify the apparent objectivity of the results of observation, or what is taken for observation. One consequence of the neglect of these and allied questions by teachers of medicine is that medical students and, later, practitioners, whilst holding as a creed that facts alone form the proper basis of medicine, and that speculation, logic, and metaphysics are alike to be abhorred, yet mistake our subjective interpretations of sense experiences (if not our verbal symbolisations of these interpretations) for facts and realities. Or, if such mistake is not consciously made, they do at any rate speak, and ultimately come to think, as if our ideas and symbolisations were really facts and data of objective experience. No one has been more insistent on the essentially fallacious quality of some of these forms of thought and expression than Sir Clifford Allbutt who, in a letter written only a few weeks before his death, lamented the persistence with which too many of us repeat, in betrayal of our own minds, foggy phrases that indicate false beliefs in the real existence of text-book "entities."

It is against these and similar verbal and mental confusions that Mr. Ogden and Mr. Richards, and their collaborators, have declared war; and a pertinent and illustrative fallacy of the kind they would combat is ready to hand. At the present moment active discussion engages as to the relations between three alleged "entities": variola, varicella, and alastrim. The question that is formally posed is whether alastrim is variola, or is varicella, or is neither, and perhaps a third object in Nature. Now, while few if any of us would be willing to admit that we are in the habit of mistaking a name for anything but a label to be fixed to something for denotive purposes, far fewer of us are willing to discuss the nature of the "things" to which the labels variola, varicella, and alastrim are at present attached. Yet, on reflection, all must admit, we think, that the "things" denoted by these names are not external objective existences but parts of our mental machinery—concepts, as some would say,—*general notions* that have been formed for the purpose of, and in process of classifying certain experiences, or individual cases, and series of cases. The true problem, then, is not that of the identity of these named "concepts"—whether or no alastrim "is" this, that, or the other disease—but, in what manner and why should we classify and arrange certain series and groups of cases, and label the classes that we form? And, in order to arrive at a satisfactory and convenient classification, for our present purposes, we should ask whether the hitherto recognised categories—variola, varicella, and alastrim—are properly derived from the particulars, or observed cases. The question as to whether there *are* two or three separate diseases corresponding to the three names is then clearly one which raises metaphysical, or at least linguistic as well as medical problems, and these should not be raised until we have clear notions as to what we mean by "a disease." If the true problem be approached in the right manner, the possibilities of common agreement are appreciable, but, so long as some maintain that there are three, and others but two, objects in Nature waiting to be distinguished, amongst which the three names should be distributed, confusion will reign.

Now the purpose which the authors of this extremely interesting book have had in view is, we take it, to furnish all those who wish to observe accurately, generalise adequately, and express correctly, with a sort of Novum Organon, an instrument with which to think, that will obviate much of the present and prevailing confusion due to the general disregard of fundamentals. It is true that the authors discuss their theory in general terms, but elsewhere, in the "Foundations of Æsthetics," they have applied their own method to the analysis of that difficult subject and to the confusions that arise in talk about the Beautiful, while in supplementary essays to the present volume Dr. Malinowski has ably shown the high value it possesses in anthropological research, and Dr. Crookshank discusses its importance in medicine. The latter writer, indeed, in earlier essays, and in his book about influenza, appears to have made some tentative advance along the path now beaten out by Mr. Ogden and Mr. Richards, emphasising the need for distinction between what he, for epidemiological purposes, calls names, notions, and happenings and which they call words, thoughts, and things. Dr. Crookshank takes up the position that at the present day, at any rate in medicine, the tendency is to confuse what in the older logic were called universals and particulars, and to treat of universals, classes, and the like—such as special diseases—as if material, or at any rate Platonic realities. He would range himself amongst those who adhere to the Conceptualist School, founded in mediæval times by William of Occam, who first clearly recognised the distinction between the "conceptual" as opposed to the "realist" and "nominalist" views, in respect of universals and classes, and names given to them. This line of thought has never been without representation in English philosophy, and has been carried on, through Hobbes, Locke, Hume, and Bentham, down to to-day. It is now permeating science, and has been ably expounded by Vaihinger, in "The Philosophy of As If."

But the authors of "The Meaning of Meaning" have attempted to cut a way through the mazes of metaphysical and logical discussion by giving, more fully than has yet been attempted, adequate attention to what they call a theory of symbols. Verbal symbols—words and phrases—stand for them as labels, as means of identification for the thoughts that, in this context, are called references. The thoughts or references have, as basis, signs, or what is thought about, and these signs are called referents. While in the simplest mental processes referents are single signs or groups of such signs, or sense-experiences, thoughts themselves may in process of higher interpretations become referents. Incidentally, so long as we distinguish between our symbols, our references, and our referents, it is, for the moment, quite unnecessary and irrelevant to bother about theories of reality, and we can, if we please, adopt the authors' method of thought and expression with equal convenience and advantage whether we be materialists of the most common-sensical variety or idealists of any school—Berkeleyan, Kantian, or Hegelian. Illustration of the applicability of the principles to medical discussion is given by Dr. Crookshank in his appendix to "The Meaning of Meaning," wherein he attacks anew the problems raised by the recent recognition of encephalitis lethargica as an entity *sui generis*, distinct from polioencephalitis and poliomyelitis. According to Mr. Ogden and Mr. Richards, our "cases" are our referents, which when accurately observed should form the "material" of our references, or disease-concepts, whilst these concepts, if adequately constructed, should, when correctly symbolised or named, yield that economy in thought which Mach held to be the object of all science. Thus we are furnished with rules for our better deportment in expression, and for correct symbolisation, so that we should not fall readily into the error of confounding our references and our referents, our symbols and our references—that is to say, our thoughts with what we observe, and our names with our thoughts and with objective or subjective "things."

The Theory of Symbols is, indeed, very completely worked out, and a Theory of Signs outlined in some detail, in a work whose implications are far-reaching. Not every chapter therein is easy reading, but every chapter contains much that is valuable, and a good deal that is amusing, while the whole lesson will be of high utility to all who desire to steer clear of the fallacies that attend the communication of thoughts to others—fallacies which have led to lack of economy in scientific and literary endeavour as well as to profound misunderstandings and thus become heavy obstacles in the path of human progress.

JOURNALS.

BIOCHEMICAL JOURNAL. Vol. XIX., No. 1, 1925. Among the contributions to this issue are the following: G. Hunter writes on the Diazo-Reaction in Urine. The subject is approached from an historical standpoint and Ehrlich's reaction is analysed. The reagent favoured by the author is that of Koessler and Hanke. An attempt is made to systematise the different types of diazo-reaction in normal and pathological urines. The Ehrlich diazo-reaction in acid solution is merely referred to, as there has never been any question of its specificity for bilirubin in biological fluids. The diazo-reaction in alkaline solution has been divided into two types, A and B. Type A reaction is characterised by a gradual development of colour until a relatively stable maximum is reached. Type B reaction is given by an immediate development and rapid disappearance of colours. All urines give some form of Type A reaction. Type B is given only by pathological urine, especially from typhoid and measles. The substance responsible for Type B reaction is unidentified, but suggestions as to its probable nature are given.—The Presence of Vitamin A in Yeast Fat is discussed by E. M. Luce and I. Smedley MacLean. Several dieting experiments were performed on rats. The results are discussed at length, three charts showing various stages of growth are given, and the possibility of synthesis of vitamin A by the yeast cell is not lost sight of.—J. M. Henderson contributes an article on the Effect of Irradiation and Diet on Calcium and Phosphorus Metabolism. One hour's irradiation daily for 24 days with a carbon arc lamp definitely increased the calcium and phosphorus retention in a pig on a badly balanced diet, as compared with a control kept in the dark. Both Ca and P in the urine rose following on irradiation; there was no concomitant increase in body-weight. In pigs fed on a satisfactory diet, well balanced particularly with respect to Ca and ($P_2O_5 : CaO - 1 : 1$) darkness or irradiation had very little effect on Ca and P retention. Analyses of the bones were in general agreement with the findings of the metabolic analyses.—The Bactericidal Action of the Blood in Certain Dietary Deficiencies is the title of a paper by G. M. Findlay and I. Smedley MacLean. They attempt to determine the effects of diets deficient in vitamins and certain other essential factors on the bactericidal power of whole blood. Experiments were made with rats and the bactericidal power of whole blood for *Staphylococcus aureus* was investigated, when the following conclusions were arrived at. The blood of normal rats, tested against *Staphylococcus aureus*, showed a killing power of 70 per cent. The blood of rats fed on a diet deficient in vitamin A and the antirachitic factor showed a reduction in killing power only after the onset of keratomalacia or some other infection. In rats fed on a diet deficient in vitamin A and the antirachitic factor, but exposed to ultra-violet light, the onset of bacterial infection and the reduction in the killing power of the blood were delayed. Rats suffering from keratomalacia as a result of a diet deficient in vitamin A continued to show a low bactericidal power of the blood after exposure to ultra-violet light. Rats fed on a diet lacking phosphorus and the antirachitic factor showed in most cases a reduction of the bactericidal power of the blood. Rats fed on a diet lacking vitamin B showed a reduction in the killing power of the blood.—In an article entitled the Early Action of Insulin on Diabetes, L. Lawn and C. G. L. Wolf attempt to throw some light on the effect of insulin upon carbohydrate metabolism. Details of four cases are given and the authors offer the suggestion that the first action of insulin is to convert glucose into glycogen, and as soon as a reasonable demand of the tissues for this substance is satisfied the insulin enables the organism to mobilise and burn the glycogen in the usual way.—A Chemical Study of Defective Ossification in Rachitic Animals, by R. Robinson and K. M. Soames. In this paper the chemical aspects of the cause and nature of rickets are studied. Numerous dieting experiments were carried out on rats; tables showing Ca and P in diets and acid-soluble P in whole blood are given as well as bone analyses; results tend to show that the defective calcification of the skeleton resulting from inefficient diets is probably not due to any deficiency of inorganic phosphate or of the specific phosphoric ester in the blood, or of the enzymes in the bone by which the ester is hydrolysed. The view is held that the defective calcification is mainly due to a deficiency of inorganic phosphate ions, while this is not the case when the defect is caused by a lack of the fat-soluble factor alone.

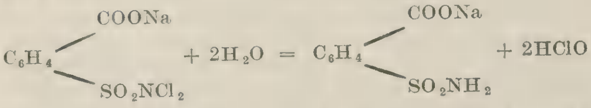
Cambridge University Medical Society Magazine. Vol. II., No. 2.—This magazine maintains its high level, and much of the present contents is interesting to other than local readers, who are the only readers who can be expected to appreciate the lighter side of the production. Mr. Vernon Pennell's essay on chronic iliac pain and Sir William Willcox's notes on fatal poisoning may be mentioned for their clinical value, while to that increasing group of medical men who are interested in the ancient story of their profession, Dr. W. H. L. Duckworth's note on Harvey's MS. Prælectiones will be very interesting. Once again we have proof of the real sterility of the intellectual world during the Dark Ages. Dr. Duckworth shows in his survey of Harvey's quotations and references that for the most part the great pioneer's sources of information as to work accomplished previously, and as to opinions published by his predecessors, were twofold—namely, the writers of antiquity and those of the sixteenth century. Between these is silence.

Reports and Analytical Records.

PANTOSEPT TABLETS.

(Manufactured by Chemische Fabrik Ehrenstein.
Sole Distributors: Barton Trading Co., Ltd.,
4, Dean Stanley-street, Westminster.)

The value of Dakin's solution—which is essentially a mixture of boric acid and bleaching powder—is well known to medical practitioners, but it has the disadvantage of requiring special preparation. Many attempts have been made to produce hypochlorous acid for medical purposes in a form which is stable, and this has apparently been effected by Prof. M. Claasz of Munich. He has found that the sodium salt of dichlorylsulphamido benzoic acid when dissolved in water decomposes as follows:—



$$C_6H_4\begin{cases}COONa\\SO_2NCl_2\end{cases} + 2H_2O = C_6H_4\begin{cases}COONa\\SO_2NH_2\end{cases} + 2HClO$$

yielding the sodium salt of sulphoamido benzoic acid and hypochlorous acid. The hydrated ($3H_2O$) sodium salt of dichlorylsulphamido benzoic acid mentioned above has been christened "Pantosept."

When "Pantosept" was analysed the following results were obtained:—

Available chlorine	15·5 per cent.
Sulphur	10·0 ,,
Sodium	15·0 ,,
Silica	2·6 ,,

Borates, sulphates, chlorides, phosphates, carbonates, and bicarbonates were absent. The silica present represents about 4·2 per cent. of sodium silicate, which has probably been used as a binding material. The available chlorine is rather lower than that calculated from the formula set out above.

"Pantosept," which is supplied in tablets, dissolves practically completely in water and the hypochlorous acid thus liberated is then capable of exercising its well-known antiseptic action. It is an ingenious and convenient form of obtaining a solution of hypochlorous acid by the addition of water to a solid material which, unlike bleaching powder, is quite stable.

ETHIDOL: ETHYL IODO-RICINOLEATE.

(Burroughs, Wellcome and Co., Snow Hill Buildings,
London, E.C. 1.)

This preparation is an outcome of the successful internal use of iodicin, a calcium salt of iodoricinoleic acid. In ethidol the calcium base is replaced by the ethyl radical and the result is a product, presenting 20 per cent. of iodine in organic combination, suitable for intra-glandular injection and inunction. Its therapeutic application is based upon its iodine content and penetrative power, and extended clinical trials have yielded evidence indicating its usefulness and justifying its introduction to the medical profession. It can be employed as an injection in rheumatoid arthritis and in the treatment of tuberculous and scrofulous glands, and has been administered in epilepsy. As an inunction successful clinical results have followed its use, again, in rheumatoid arthritis and in simple goitre; and, in view of its iodine content, its further trial is suggested in sprains, neuritis, and some skin affections such as eczema, psoriasis, ringworm, and erysipelas. Ethidol does not stain or cause local irritation. It may be heated to 100° C. before injection, which appears to be attended with no discomfort. Injections are stated not to cause induration and are usually painless. The strength can easily be modified as the preparation is miscible with almond or olive oil. It is issued in bottles of 1 oz. and 4 oz.

THE "SOLOID" URINE-SUGAR-TEST CASE.

(Burroughs, Wellcome and Co.)

The above firm has also put upon the market a sugar-test case for the use of diabetics who are under insulin treatment at home. The case is made of stout cardboard and contains a liberal supply of tests, 24 in all. The full contents are as follows: Two tubes of "soloid" alkaline citrate, one tube of "soloid" copper sulphate, one medicine dropper with rubber bulb, two test-tubes graduated, one wire test-tube holder, one small square of asbestos, one bottle of 25 "soloid" hexamethylenetetramine, and one of these placed on the asbestos square will burn for three minutes, sufficiently long to conduct one test. The test is very reliable, and amounts as low as 0·1 per cent. of glucose are read with ease. The introduction of a simple heating medium, obviating the employment of methylated spirit, is a feature which will be readily appreciated. The flame is smokeless and therefore there is no tendency for the reading to become obscured. The case is compact, measuring 5 in. × 4¼ in. × 1⅛ in., and may easily be carried in the pocket. The price is 5*s.* 5*d.*

GOLDEN CORNISH CLOTTED CREAM.

(Mawnan Farms, Ltd., Mawnan, Falmouth.)

We have received from Mawnan Farms, Ltd., a sample of the cream which they distribute as specially suitable for invalids and delicate children, and, judging from the letters received from medical men, it appears that the manufacturers are supplying a really useful thing. The cream is sent direct from the farm fresh daily, absolutely pure and free from preservatives.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 21st, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—Small-pox, 133; scarlet fever, 1718; diphtheria, 878; enteric fever, 36; pneumonia, 1523, puerperal fever, 55; cerebro-spinal fever, 12; acute poliomyelitis, 5; encephalitis lethargica, 63; continued fever, 1; trench fever, 1; dysentery, 15; ophthalmia neonatorum, 137. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases showed a decrease of four from the number for the preceding week. Twenty-nine cases were notified from Derbyshire (Derby C.B., 25); 23 from County Durham (West Hartlepool C.B., 21); 16 from Northamptonshire (Kettering, 14), 12 from Northumberland, 12 from Notts, and 25 from Yorks, North Riding (Middlesbrough C.B., 25).

Deaths.—In the aggregate of great towns, including London, there were 5 deaths from enteric fever, 127 from measles, 11 from scarlet fever, 155 from whooping-cough, 39 from diphtheria, and 304 from influenza, as compared with 283, 361, 346, and 352 in the four preceding weeks. In London itself the deaths from influenza numbered 48, from whooping-cough 41, and from diphtheria 12.

THE LANCET.

LONDON: SATURDAY, APRIL 4, 1925.

THE PENALTIES ON PANEL DOCTORS.

THE Panel Committee for the County of London recently reported adversely to the Ministry of Health on the medical conduct of a panel practitioner, and accordingly the Inquiry Committee appointed for the purpose by the Minister of Health investigated the circumstances, with the result that the charge of gross negligence, formulated by the Panel Committee, was considered to have wholly failed. The Inquiry Committee added that as the Panel Committee had not been justified in making the representation and in putting in motion the machinery, they would have to pay to the practitioner his taxed costs of the inquiry, while it was resolved not to remove the name of the practitioner from the medical list. At the same time, however, the Inquiry Committee agreed with the recommendation of the Panel Committee that a substantial reduction should be made from the practitioner's remuneration, in accordance with which the sum of £20 has been, or will be, withheld by the Minister of Health from the money payable to the Committee in respect of medical benefit, which sum will be recovered from the practitioner. Other cases dealt with by the Inquiry Committee resulted in the censure of a practitioner for the irregular charging of fees for drugs to an insured person, and in the acquittal of a practitioner for gross negligence in failing to pay certain visits to a case of appendicitis. But in this case, as in the case first referred to, the acquittal of the charge of gross negligence was qualified by a fine of £10 for failure to provide a proper standard of medical treatment; while other practitioners, concerning whose conduct of their work complaints had been made, were fined small sums for not complying with certain terms of the service, for not keeping proper records, or for irregular acceptation of fees.

These proceedings have aroused considerable interest in the panel service who, to a man, bear in mind the case of a monstrous fine recently inflicted in analogous circumstances, and the feeling is becoming widespread that the powers of the Ministry of Health in dealing with accusations against panel practitioners are improperly arbitrary. It is not difficult to see how these powers, which are not only unprecedented but were never contemplated when the National Health Insurance Act was passed, have come into being. The Minister of Health is responsible to Parliament for seeing that insured persons get their rightful benefits under the Insurance Act, and accordingly has to see that the insurance practitioners carry out their contracts. Therefore, he must have some punitive discretion, and it will be admitted that, to prevent the occurrence of illegalities or abuses, penalties constitute a reasonable procedure. But a procedure which is reasonable in concept may in practice become the reverse, and it is difficult to understand on what grounds practitioners can be fined by a tribunal which holds that the indictments were incorrect; while it is comic, though the results may be tragic, that there should be no limit apparently to the fines that may be demanded. In our Parliamentary report this week will be found an interrogation put to the Minister of Health, inspired by two of the cases alluded to above, but having a general bearing on the whole matter. The Minister of Health explained the action of his Department on the ground that, while gross negligence was not established in either case, failure to exercise reasonable care in one of them and to visit at a critical period in the other, were indicated. This is a perfectly straightforward reply, and it is no reproach to the Minister that it will not be found sufficient. The Minister of Health cannot and does not attempt to prescribe the medical treatment which should be given, and which, we presume, must be settled by the professional standards which hold good for the area in which the medical man practises. The practitioner who acts in any circumstances "to the best of his knowledge and belief" should not be penalised. Here we would remind those who are most critical of the valuable services rendered to the country by insurance practitioners that, when they assume modern methods of diagnosis as essential to a correct diagnosis, they are ill-informed, and may in many respects be belittling the whole of clinical practice. These are the persons who initiate the actions for malpraxis or negligence brought against medical practitioners, where, whatever the verdict, pecuniary and professional damage to the doctor and expenditure of money by the complainant are the inevitable results.

But we do not expect the Ministry of Health to react in accordance with what are conceived to be public demands. The Minister of Health has responsibilities towards his officers as well as towards the public, of whom his officers are also a part. The knowledge that disciplinary inquiries will be made upon rightful occasions, and that penalties will be meted out logically in accordance with undisputed findings, encourages those insurance practitioners who need the stimulus to comply with the terms of the service. But the feeling that a man can be penalised when the indictment breaks down, the apprehension that a Committee of Inquiry may not be able to detect when the views of a Panel Committee represent a reasonable estimate of what should be demanded of a practitioner, and any capricious or vindictive fines—these things do not encourage good work.

◆

RADIUM THERAPY.

THERE has been published this week a clinical index of radium therapy, written by Mr. A. E. HAYWARD PINCH, medical superintendent of the Radium Institute, with the object of bringing to the notice of medical practitioners generally the wide range of diseases covered by this branch of therapeutics. The cost of the publication is being borne by the Committee of the Institute, and the volume is intended for gratuitous distribution to the medical profession. The book is based upon the actual work carried out at the Radium Institute, clinical signs and symptoms are recorded as well as the lines of treatment adopted and the results obtained, and in all cases the evidence has been derived from a study of the patients' case-sheets. Emphasis is laid upon the salient clinical facts by which the different diagnoses were established and in accordance with which the advisability of radium treatment was determined, while little or no attempt has been made to deal with the ætiology and pathology of the diseases concerned, and, similarly, questions of apparatus and technique, exposure, and dosage have been dealt with briefly. But a short introductory chapter sketches the physics of radium, and this must be read carefully if the information put out is to be read with understanding. As during the period which has elapsed since the opening of the Radium Institute in 1911, the annual reports of the medical superintendent have been regularly reviewed in these columns, it follows that much of this clinical index has been brought in detail before our readers on previous occasions, but undoubtedly the collection and collation of this previous work in chapters whose length indicates the relative importance of each subject to the practitioner will be valuable to many readers in whose recollection the serial notices may not be fixed. We congratulate the author upon a valuable compendium, bringing up to date in simple terms our knowledge of radium therapy.

The rationale of radium therapy is based upon the fact that the radium irradiation properly administered upon any living cell produces certain effects, occurring in three phases—namely, increase of cell activity, arrest of cell growth, and degeneration and destruction of the cell. But this fact is supplemented by another—namely, that pathological cells and normal cells respond differently to the action of radium rays, the three phases of transformation being distorted, so that proliferation is more rapidly brought about, activity is more quickly arrested, and degeneration occurs more rapidly. On this point Prof. Sidney Russ,[1] discussing the selective action of the rays in passing through the tissues of the body, has said that the rays exert some degree of selective action upon malignant and normal tissues, it being more than probable that the series of events following irradiation is determined somewhat by the interplay of forces between them. He finds, in fact, "the sequel to tumour irradiation depends not only on the dose which it has received, but on the nature and extent of the reaction of the normal tissues of the host." The chief importance, then, in the treatment of malignant disease by radium is to kill malignant cells with as little damage to the healthy cells of the body as possible, and the main problem of radium therapy is correctly to estimate the dosage and exposure necessary to bring about the death of the pathological cells without damaging normal cells beyond the point of satisfactory repair. Insufficient dosage may bring about only a quick stimulus of what it is proposed to destroy. Too heavy dosage may produce the destruction of what it is necessary to conserve. Mr. Hayward Pinch, speaking in very general terms of the fundamental principles of radium therapy in dealing with a malignant growth, advises that every effort should be made to secure as uniform a radiation as possible to all parts of the growth, and considers that it is best to give a maximum dose at the first exposure.

The latter half of the book is taken up with summaries of the use of radium in diseases of the alimentary canal and its accessory glands, the thyroid, thymus, and spleen, and the lymphatic system, with chapters on the results in diseases of the breast, and in gynæcology, urology, dermatology, ophthalmology, laryngology, and rhinology or otology generally. Radium in internal medicine is briefly considered, and the clinical aspects of the work of the research department between May, 1919, and December, 1924, are summarised by Dr. J. C. Mottram, director of the pathological laboratory. An appendix is added by Mr. W. S. Alton, the Director of the Chemical and Physical Laboratory of the Institute, which deals with the evolution of the present-day technique of preparing radium and radon applicators. This is particularly timely, as a misconception has been disseminated with respect to radium emanation, probably due to the fact that only comparatively recently the term radon has been adopted in accordance with a suggestion made in 1923 by an international committee on chemical elements. The technique of the radium emanation treatment has, no doubt, been modified, but, as Mr. Hayward Pinch points out in our correspondence columns, the method has been employed almost since the opening of the Institute, as will be seen by the details supplied in the report of the Institute for 1912. Since this time radium emanation tubes have been placed with increasing frequency in proper hands by the Institute, a procedure which also is followed at the Manchester and District Radium Institute under the supervision of their radiologist. The general conclusion of Mr. Alton is, that there is no distinction to be made in their therapeutic uses between radium and radium emanation, reference being made to a chart, included in the Clinical Index of Radium Therapy, to show that they are successive members in the disintegration series of the same parent body. Employment of one or the other can therefore be dictated by the various circumstances of the case.

◆

HOSPITALS AND THE BURDEN OF RATES.

At the last annual general meeting of the governors of the London Fever Hospital Sir Charles Stewart was able to report an improvement in the financial position. This admirable institution nevertheless increased its debt last year, though the debt would have been diminished had the hospital not been burdened with heavy demands for local rates. Sir Mackenzie Chalmers, the chairman of the meeting, raised an old, but none the less an exceedingly interesting, point by suggesting that hospitals should claim to be exempted from rates representing expenditure in which they have no interest. It is undeniable that a hospital benefits by expenditure which the local authority incurs over sewerage, the removal of house refuse, and the maintenance and lighting of the adjacent roads. It may also be said to benefit by the potential protection of the police force and the fire brigade. On the other hand, a hospital has no very direct interest in the outlay—however small its proportion—under the Baths and Washhouses Acts or the Public Libraries Acts, or in the major expenditure on education or poor relief, or on the equalisation of London rates which unemployment and the industrial crisis have made so burdensome.

It is easy to ascertain the nature of the expenditure for the payment whereof our rates are levied. Parliament could soon determine which are the items by which a hospital actually and directly benefits. If hospitals were rated in respect of those items alone, their struggle for existence would be much less acute, and the public would be the better served with improved facilities for treatment. Though Sir Mackenzie Chalmers's plea is not for the total exemption of hospitals from rates, the fact remains that in many not wholly dissimilar cases exemption is given by law. In addition to county and municipal property, for example, churches, chapels, and certified places of religious worship, lighthouses, drill-halls, and scientific and literary institutions are exempt. The basis of the discrimination is doubtless the rendering of essential public service without commercial considerations of profit or dividend. Nobody alleges that these exempted premises or undertakings are unfairly subsidised at the expense of the general ratepayer. Why should not hospitals of approved service be entitled to some relief? With the assent of all parties Parliament has given agricultural land a 75 per cent. exemption from various rates. The object—and a very proper one—is to preserve our agricultural system from extinction even at the risk of putting private profit in the farmer's pocket. Is not our hospital system worth preserving, where no question of private profit can possibly arise? The case for the London Fever Hospital is strong. Founded as long ago as 1802, it has played its part in freeing London from serious epidemics; it has trained generations of expert fever nurses; and its expenses are necessarily high because it must maintain its resources at full strength to meet emergencies. If it asks for relief from the burden of the rates, a debating point may be made against the request. The hospital prides itself on the facilities it offers to those patients who prefer to contribute towards the cost of their treatment rather than to become inmates of a rate-supported institution. A hospital which exists for those who prefer not to throw themselves upon the charity of the rates is in a dialectical difficulty in soliciting relief from local taxation.

---

[1] The Lancet, 1923, ii., 1314.

Meanwhile, the boot is on the other leg, for the London Fever Hospital as a ratepayer is at present contributing to the cost of running the institutions of the Metropolitan Asylums Board. Local authorities, of course, are hardly in a position to be generous. If they had both the means and the will to relieve a hospital, the legal doctrine of ultra vires and the threat of an auditor's surcharge stand athwart their purpose. Parliament should consider the question. Institutions which play an honourable part in the public health scheme of the country, and which are administered on sound lines and without extravagance, should not be allowed to be crushed out of existence beneath the weight of either local or imperial taxation.

◆

BRITISH CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.

We publish elsewhere the detailed information concerning the fifth British Congress of Obstetrics and Gynæcology which will be held in London from April 22nd to 24th inclusive. These gatherings from their inception have endeavoured to promote coöperation in clinical research among obstetricians and gynæcologists in Great Britain and Ireland, and those who know our "Extra Number" dealing with modern methods in abnormal and difficult labour will recognise how many points in diagnosis and in treatment remain matters of opinion, even where general lines of practice are accepted. This is particularly the case with puerperal fever, eclampsia, and dysmenorrhœa, and local committees have been formed by the constituent societies of the Congress, charged with the duty of preparing reports upon one of these subjects yearly, the first being the subject for this year. The result of such coöperative effort, and of the periodical conferences, has been undoubtedly to develop a spirit of unity and a desire to promote serious work, and already many questions have been settled. We may contrast the position to-day with that of some 20 or 25 years ago, when a paralysing discord prevailed, England and Wales, Scotland and Ireland having diverse views, while the same might be said not only of metropolitan and provincial schools, but of schools in the metropolis itself. A far greater unity exists to-day in the development of our midwifery service, and if the things which remain for settlement are numerous every advance in our scientific knowledge adds to the list. There will always be work ahead, and the influence of the impending Congress, like that of its predecessors, will be towards the establishment of views which represent accord between the obstetrical teachers of Great Britain and Ireland.

Annotations.

"Ne quid nimis."

THE USE AND ABUSE OF DRUGS.

In the middle of last century the doctrine of therapeutic nihilism found its chief exponent in Josef Skoda, a leader of a new school of thought in Vienna, who declared that while we can diagnose and describe disease we dare not expect by any means to cure it. In this country up to the present day the influence of that doctrine persists—diagnosis is taught in our medical schools as the essential equipment of the young practitioner, and the student hears too often that a physician must be judged, not by the success of his treatment, but by the extent of his knowledge, medicine as the art of healing the sick giving place to medicine as the study, per se, of the disease. But the tide of opinion is turning against therapeutic nihilism, and Prof. W. E. Dixon, at a meeting of the Hunterian Society on Monday, March 30th, stated as one of the reasons which have altered our views on the action of drugs, that we have now learned that the body itself works by means of drugs of its own manufacture. It manufactures alkaloids, just as plants do, for its own needs. In emergencies our internal secretions may provide us with drugs required for our well-being—in rage or fear a rush of adrenalin will produce the conditions required for fight or flight. Chemotherapy is also opening up a new outlook in medicine with regard to specificity, and, while increasing specificity in pharmacology widens the field of successful treatment of disease, it also increases the possibilities of the abuse of drugs. It is a difficult matter to draw the line between use and abuse of a drug. For example, quinine is a specific for malaria, but its use to treat a cold may be classed as an abuse so long as there is no definite organism susceptible to quinine and ætiologically connected with the cold. Dr. H. H. Dale, speaking at the same meeting, defined the abuse of drugs as their reckless and unintelligent use. Intelligent use of a drug, he explained, did not mean that the practitioner must have a full scientific appreciation of a drug's action; were that necessary many valuable drugs would require to be discarded. But it was essential to make close and accurate clinical observations, and not to rely on vague impressions and rule-of-thumb restrictions. Enlightened empiricism he described as being often a better procedure than basing treatment on a supposedly scientific foundation. Much is now being published both by scientific and lay writers concerning the rationale of the action of certain pharmaceutical products, and it is couched in scientific or pseudo-scientific terms whose main characteristic is extreme plausibility. Many of these "scientific" explanations contained in pharmacological "literature" Dr. Dale considered to be dangerous, the danger lying, in his opinion, in the excessive modesty of the medical profession who were inclined to look on what they could not quite understand as being very deep and possibly very true. It was impossible, he pointed out, for anyone to know more than his own corner of the scientific world, and such an attitude of accessibility to mysterious dicta coming from another corner was to be deprecated. As an instance of this Dr. Dale quoted several statements that had been made on the one hand with perfectly genuine intent by a leader of the medical profession with regard to the value of colloidal substances, and on the other by a firm of commercial chemists, perhaps not so ingenuously; but both sets of utterances were entirely misleading. It was time, he said, that something was done to rescue what might be valuable in treatment from what might be manifest abuse, but the difficulties in differentiation are considerable. This should not, however, cause them to be held insuperable. We congratulate the Hunterian Society upon having elicited at their last dinner meeting such wise speaking on an important topic. The dinner was held at Simpson's Restaurant, Cheapside, and was well attended.

THE FIGHT AGAINST MALARIA.

Last summer the Malaria Commission of the League of Nations Health Organisation undertook a tour of three months for the study of the incidence of malaria in Eastern Europe, visiting Italy, the Balkans, and Russia, and much valuable information was obtained. This year, from May to September, the Commission is extending on similar lines its inquiry into malaria conditions prevailing in Egypt, Palestine, Syria, eventually Turkey and Asia Minor, Sicily, Corsica, and Spain. At a session now in progress the Commission, which consists of experts from Great Britain (represented by Colonel S. P. James, of the Ministry of Health), France, Germany, Italy, Poland, Rumania, and Holland, is considering a final report on malaria in Albania prepared at the request of the Albanian Government, a request from the Turkish Government for the appointment of an expert to help in organising an anti-malaria campaign in Turkey, and a note from the French Government asking for a special inquiry in Corsica. Finally, the Commission will consider the appointment of additional corresponding members from British India, the United States, and France, and a report on the question of the employment of quinine and other cinchona alkaloids against malaria. Owing to the depreciated exchanges, this question of the cheapest and most effective drugs to use against malaria is of fundamental importance in the work of the Health Organisation on this subject.

THE PROGNOSTIC SIGNIFICANCE OF SCARLATINAL NEPHRITIS.

Our knowledge is still very incomplete as to the duration of the damage inflicted by an attack of scarlatina on kidneys which, through the acute stage of the disease, have reacted with albuminuria. Is, for example, the small granular kidney, with which we are so familiar in the post-mortem room, the final stage of a series of events beginning with a bout of scarlatina ? And how long do most cases of scarlatinal nephritis last before albumin disappears from the urine, and what effect, if any, does scarlatinal nephritis have on the development of orthostatic albuminuria ? These are some of the questions which Dr. H. Hansborg, of the Blegdam Fever Hospital in Copenhagen, attempts to answer in a paper published in *Acta Medica Scandinavica* for Feb. 12th. In the 10-year period, 1911-1920, his hospital admitted 75 per cent. of all the cases of scarlatina notified in Copenhagen. Among the 14,339 cases of scarlatina admitted in this period, there were 612 complicated by hæmorrhagic nephritis. After subtraction of the cases which proved fatal in the acute stage of the disease, there remained 588 patients, 284 of whom were re-examined from one to ten years after discharge, the heart and blood pressure as well as the urine being investigated. Dr. Hansborg made a point of examining the morning urine in those cases in which orthostatic albuminuria was suspected, and he found that among the 284 ex-patients there were 23 who were suffering from albuminuria which was merely orthostatic. There was one patient found to be suffering from chronic nephritis, the characters of which distinguished it from that of scarlatina, and there was only one patient whose albuminuria, which had lasted for five years, could be reasonably regarded as a sequel to the scarlatinal nephritis. As many as 259 of the re-examined ex-patients showed no evidence of renal disease. Of these 259 patients, as many as 235 were already albumin-free when discharged from the fever hospital. Several of the remaining 24 patients took more than a year after discharge to get rid of their albuminuria. With regard to the 23 patients found on re-examination to be suffering from orthostatic albuminuria, Dr. Hansborg raises the question, May this condition be the result of a hæmorrhagic nephritis developing during an attack of scarlatina ? One of his reasons for answering this question in the negative is that the frequency with which patients who had suffered from scarlatinal nephritis developed orthostatic albuminuria was no greater than the frequency with which this condition occurs in the general population at the same age. Besides, there was no relation between the severity of the scarlatinal nephritis and the frequency of the subsequent orthostatic albuminuria. Additional value would be given to Dr. Hansborg's investigations and reassuring conclusions if the former were to be repeated on the same material some score of years hence.

ACTIVATED CARBON.

Ordinary charcoal, and especially bone black, is well known to possess considerable properties of decolorising liquids, absorbing gases, and promoting chemical reactions. Of recent years a modification of the element has been prepared known as activated carbon in which these properties are very highly developed as compared with the best bone black or any other hitherto known variety of carbon. In activated carbon the pores are of almost incredible smallness in size and have entirely porous walls which are not clogged up with impurities, so that the chemical reactivity of the material, on the principle of what the chemist terms "surface action," is improved out of all proportion. The methods of manufacture are complicated and require great experience, one general process, for example, being to carbonise under regulated and definite conditions carefully prepared carbonaceous mixtures, followed by an elaborate purification and extraction. In connexion with the manufacture it is right to mention the firm of Sutcliffe, Speakman, and Co., Ltd., of Leigh, Lancashire.

An important technical application of activated carbon is the extraction and purification of gases, especially the direct separation of motor spirit from the crude gases evolved in the carbonisation of coal, shale, and other carbonaceous material, by the use of a bed of the material. When this is saturated steam is blown through, and the motor spirit recovered in an extremely pure condition, thus eliminating a considerable amount of expensive fractionating plant. In the same way solvent naphtha and other solvents can be recovered and purified, and another valuable outlet is the absorption of obnoxious smells and vapours. The decolorising of oils and fats on these lines is almost entirely a new field and important developments are pending, the method being of considerable advantage for the purification of tallow, coconut oil, linseed oil, peanut and corn oil, cotton-seed oil, and castor oil. In the latter case, for example, fuller's earth is at present used, but the addition of activated carbon, about 5 per cent. by weight, gives far superior results. For solutions the material is finding the most extensive application, especially for cane-sugar, glucose, brewing sugars (maltose and lactose), tartaric acid, cream of tartar, citric acid, lactic acid, and organic compounds used as intermediates in dyestuff manufacture, together also for the extraction of gold from excessively dilute solution 1 part per 10,000,000 in the cyanide process. The purification of ordinary alcohol and the extraction of higher toxic alcohols (fusel oil) is another similar application. In applying the treatment to liquids generally the activated carbon is as a rule simply stirred up with the heated liquid for a short period and then blown through filter presses, the product being subsequently revived by various methods after acting for a number of times. Thus it may be boiled with water, re-burnt, or treated with acids or alkalies, and the method is capable of almost endless applications, especially, as already indicated, different carbons may be supplied for absorbing different materials, whether from liquids or gases. Activated carbon possesses considerable interest from a medicinal point of view since it is used in the tablet or powder form for the correction of flatulence, dyspepsia, and diarrhœa, and is said to be much superior in this respect to ordinary powdered charcoal. Indirectly it is of great value also in many different directions in the manufacture of pharmaceutical products, both for decolorising and purifying. It is also employed in the preparation of strychnine, quinine, brucine, and other alkaloids, and in connexion with very many different drugs such as antipyrine and phenacetin.

THE SEX INCIDENCE OF CANCER.

WE have been told for so long and by so many authorities that cancer is much more frequent in women than in men that we are inclined to regard as unorthodox and heretical the view that the sexes suffer equally in this matter. The view that cancer is more frequent in women is based on the obviously true statement that cancer of the reproductive organs attacks women much oftener than men; the greater longevity of women is also said to be a reason why they are supposed to be more subject to cancer than men. Some recent investigations suggest that the comparative immunity of males to cancer is fictitious, depending on the fact that the forms of cancer which are most deep-seated, and therefore most easily overlooked, are more common in men than in women. A recent paper by Dr. A. Renaud[1] of Lausanne contains an informing statistical statement on the notifications of deaths from cancer throughout Switzerland in the period 1901-20. It is interesting to observe with regard to these notifications that carcinoma and sarcoma are kept apart, and that when a patient suffering from cancer dies of bronchopneumonia or myocarditis, for example, the cause of death is notified as cancer and not as a disease of the lungs or heart. The average annual mortality in Switzerland during the 20 years under review was 4717, males being represented by 2347 and females by 2370 deaths. Considering that women outnumber men, it might even be argued that the risk of a man dying of cancer in Switzerland is even a little greater than the same risk for a woman. As Dr. Renaud calculates, among persons over the age of 40 the annual cancer death-rate in the period under review was 1 per 214 men and 1 per 243 women. He notes in this connexion that experimental cancer in mice is equally common in the two sexes. Among his Swiss cases, as great a proportion as 73 per cent. of all the cancers in males affected the digestive tract, notably the œsophagus, stomach, and rectum, whereas this localisation was comparatively rare in females. Indeed, in the case of cancer of the œsophagus, the ratio of males to females was as 6 to 1. In another recent publication Dr. F. G. Gade[2] has pointed out that in Norway women with 51·8 per cent. of all the malignant tumours are at first sight a little worse off than men with 48·2 per cent. But as 51·3 per cent. of the population in Norway in 1920 were females, it appears that in Norway as well as in Switzerland malignant disease is equally distributed between the two sexes. It would be interesting if the cancer statistics of other countries, which have hitherto been supposed to show a preponderance of malignant disease in women, were to be revised in the light of the statistics from Switzerland and Norway.

THE LAST ILLNESS OF PRESIDENT EBERT.

THERE were special reasons why no mystery should be allowed to attach itself to the circumstances of the death of the late German President Ebert, and his medical advisers have, accordingly, published a full account of his last illness and the partial post-mortem examination. The authors of the report, "Bericht über Krankheit, Operation und Tod des Reichspräsidenten Ebert," which is published in *Deutsche medizinische Wochenschrift* for March 13th, are Dr. A. Freudenthal, the President's family doctor, Prof. A. Bier, who operated on him, and Prof. O. Lubarsch, who examined the contents of the abdomen after death. It appears from Dr. Freudenthal's account that Ebert, who was 54 years old at the time of his death, had suffered for a few years from occasional attacks of biliary colic which, on one occasion, was associated with jaundice. He had been ailing since Christmas, when he contracted what appeared to be an attack of influenza, and in February of this year he was complaining of lassitude, loss of appetite, and a cough. On the morning of Feb. 23rd he complained of pain in the liver region, and tenderness was observed over the gall-bladder. Elsewhere the abdomen was flaccid and not tender. A violent attack of abdominal pain began in the late afternoon of the same day, and on this occasion there was marked tenderness over the appendix with slight muscular rigidity. The rest of the abdomen was flaccid. At 8.45 P.M. of the same day the temperature in the axilla was 37° C., the pulse was 72, and there was an increase of the tenderness and rigidity over the appendix. An injection of morphine was given, and Prof. Bier was summoned. It was agreed that an operation should be performed at once, and Ebert was taken to a hospital where he was operated on at midnight. Much cloudy, odourless fluid was found in the peritoneal cavity, and the intestines were seen to be much distended and injected. The appendix, which was very difficult to find, was gangrenous and perforated. For several hours preceding death, which occurred on Feb. 28th, the clinical picture was characterised by intractable intestinal paralysis. At the necropsy the gall-bladder was found to contain calculi, and there were ulcers of the stomach, one of them extending down to its muscular layer. The lining of the small intestine was necrotic in places, and it was probable that the changes in its walls were not altogether recent. Indeed, it seemed that the intestinal paralysis, which contributed so much to the fatal issue, depended not only on the inflammation of the peritoneum, but also on the diseased condition of the mucous lining of the stomach and intestine. The interval between the onset of vague abdominal symptoms and the operation was one of 20 hours, and seven hours between the detection of signs of appendicitis and the operation. One of the many features of this case which is of interest to the surgeon is the liability of a history of recurrent attacks of biliary colic to delay the diagnosis of an acute attack of appendicitis. Passing from this isolated case to generalities it is interesting to note that, as a rule, much greater publicity is given to the causes of death of distinguished persons abroad than in this country. Reticence in such matters is, of course, natural, but there is much to be said in favour of the course taken by the medical advisers of Germany's first President.

CARBOHYDRATE METABOLISM DURING PREGNANCY.

SINCE the introduction of insulin, all alterations in carbohydrate metabolism have received additional attention. Ehrenfest,[1] in a recent article, considers the matter very fully. So long ago as 1895 it was shown by V. Jaksch that 100 g. of glucose taken by mouth would cause a glycosuria in the majority of pregnant women; this amount has no effect on non-pregnant ones, and certain tests for pregnancy are based on this fact. The routine testing of the urine of pregnant women has shown that glycosuria as estimated clinically is not uncommon in these subjects, and the improvement of technique in the estimation of blood-sugar reveals the explanation of this phenomenon, which lies apparently in the lowering of the "renal threshold" for sugar. There are, however, other factors at work. During pregnancy the whole of the endocrine system is in a condition of hyperactivity. The increased activity of the thyroid which has been proved to exist results, according to Olmstead and Gay, in an increased metabolism, a delay in glycogenesis, or augmented glycogenolysis. It is well known, too, that increased activity of the adrenal tissues results in glycogenolysis with a resulting hyperglycæmia and glycosuria. That pregnant women are abnormally sensitive to injections of adrenalin is known, and all evidence suggests that in them the adrenals are in a state of hyperactivity. The difficulty in assessing the action of the ovarian secretions is very great on account of their multiplicity. Some interesting experiments by Kuestner show, however, that a secretion from the ovary of pregnant animals is responsible for a lowering of the sugar tolerance. The increased activity of the pituitary during pregnancy is familiar, and this factor considered alone results again in the lowering of the sugar tolerance. In spite of an alteration in all these factors having a bearing on sugar metabolism, authorities agree that the blood-sugar concentration in healthy pregnant women varies within the normal limits. We must conclude, therefore, that although metabolism takes place on a higher rate, it remains normal. The lowering of the renal threshold for sugar may be a protective mechanism against the effects of hyperglycæmia on the fœtus.

INDUSTRIAL ACCIDENTS AND DISEASES.

A medical congress, the Fourth International Medical Congress for the Study of Industrial Diseases and Accidents, will be held in Amsterdam in September, commencing on Monday, the 7th, and concluding on the following Saturday. This is the first representative meeting of medical authorities to be held since the war, and so much work has been done in this country along the whole line that we may expect our delegates to play a prominent part in the conference. The President of the Congress is Dr. P. H. van Eden, of Amsterdam, and the British Executive Committee consists of Mr. R. de Marees van Swinderen, the Minister of the Netherlands (Hon. President), Sir Thomas Oliver and Prof. E. L. Collis, as President and Vice-President, respectively, and the following members of Committee: Dr. D. A. Coles, Sir William Collins, Prof. J. Glaister, Sir K. W. Goadby, Sir William Hale-White, Sir Robert Jones, Dr. J. R. Kerr, Dr. A. Mercer, Dr. Howard Mummery, Dr. A. Scott, Dr. Theodore Thompson, Dr. A. Trimble, Dr. H. M. Vernon, Dr. Thomas Watts, M.P., and Dr. R. Prosser White. Dr. C. S. Thomson is Hon. Treasurer, and Dr. H. Menko, 2, Grosvenor-gardens, London, N.W.2, is Hon. Secretary, from whom full particulars may be obtained. It will be seen that the constitution of the Committee warrants the expectation that they will make practical contributions to international wisdom on a difficult subject.

PROF. GUIDO BANTI.

Guido Banti died early in the year, aged 72, at Montebicchière in Florence, the place where he was born and from which he rarely moved. For 35 years he was director of the Institute of Pathological Anatomy in Florence and also physician to the Hospital of Santa Maria Nuova, where he had 150 beds. A retiring man of the true scientific type, he was personally hardly known outside his own country, but Banti's disease has made his name familiar to the whole world of medicine. Two notices of him by former pupils (*La Riforma Medica*, Jan. 28th, and *Rivista Sudamericana di Immunologia*, Feb. 15th) depict a man who was deeply beloved and admired by his students, one who had a great reputation both as a clinician and pathologist, though his outspoken frankness and tendency to regard the patient rather as a scientific problem prevented his being successful as a physician with the public. He was not a voluminous writer, but his published works covered a considerable range of subjects. Almost his first work was on aplasia, in which he tried to enlarge the somewhat narrow teaching of the French school. In 1881–82 there followed contributions on the progressive anæmias and on splenic anæmia; in 1886 one on the bacteriology of cerebral meningitis. His theses on splenic anæmia,[1] in Italian, attracted little attention, but in 1894 he published papers both in French and German journals on splenomegaly with cirrhosis of the liver, which won him recognition as a great clinical observer and has caused his name to be indissolubly associated with that type of the disease. In 1895 he published a short work on endocarditis and nephritis, and in 1902 one on the pathology of the lung. In 1905 there appeared the first numbers of a great work on pathological anatomy, but this, unfortunately, was never completed, partly owing to his having suffered for years from writer's cramp. From 1908–17 he was editor of the *Rivista Patologica Quindicinale*, published at Genoa, and he made no further individual contributions to medicine. It will be seen that Banti's work covered a considerable field. He had a keen, independent, and progressive mind and an immense store of clinical and pathological experience and he was an indefatigable worker. His papers are excellent examples of close reasoning, based on keen observation and great knowledge; they are neither dogmatic nor obsequious to received opinion. There is little doubt that had he written in a language more generally accessible to physicians, he would have attained a much wider reputation, one that would have justified all that his countrymen thought of him.

THE NEW FACTORIES BILL.

It is an open secret that the prospects of this Bill have been much improved by the stream of steady explanations which has been forthcoming from experts on the subject. Many Members of the House of Commons have taken advantages of opportunities for real comprehension of the views of those who see in the Bill an overdue measure for righting certain manifestly wrong positions, and in this way apprehensions of unduly burdening the factory owners are, we think, being dissipated. At the University of Birmingham this week Miss L. Carbutt, who has acted as a temporary Inspector of Factories, gave a lecture under the auspices of the Y.W.C.A. Industrial Law Bureau, in which she drove home those general points that have been emphasised in the press, while she added an argument of considerable force for reform when she stated that in a large Birmingham factory during the past winter the women had worked throughout every Saturday afternoon, bringing their total work for the week up to 60 hours. The Government can see, therefore, that the legislation which is definitely included in their programme is necessary as well as widely desired.

As already announced in The Lancet, an International Congress on Thalasso-Therapeutics will be held at Arcachon from April 22nd to 25th.

The House and Library of the Royal Society of Medicine, 1, Wimpole-street, London, W., will be closed from Thursday, April 9th, to Tuesday, April 14th, both days inclusive.

An extraordinary general meeting of the members of the National Council for Combating Venereal Diseases will be held at the Board Room of the Girls' Friendly Society, 39, Victoria-street, London, on Monday next, April 6th, at 4 p.m., to consider and, if thought fit, to pass the following extraordinary resolution: "That the name of the company be changed to the British Social Hygiene Council." Should the resolution be passed by the requisite majority, it will be submitted for confirmation as a special resolution to a second extraordinary general meeting which will be subsequently convened.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXVI.—TREATMENT OF ACUTE PERITONITIS.

Acute general peritonitis is nearly always, unless it is a terminal condition, the result of a sudden incursion into the peritoneum of infecting organisms from a local source of supply. There are many causes, but by far the great majority of cases will be found to originate in a perforated appendix or a perforated gastric or duodenal ulcer. Less frequent causes are ruptured tubes, ruptured gall-bladder, acute pancreatitis, traumatic perforations—e.g., a kick in the abdomen—and so forth. The main point in the treatment is to establish the diagnosis at once, open the abdomen, stop the leak, and provide for the removal by drainage of the products of the leakage.

Signs of Peritonitis.

The signs of a general infection of the peritoneum are as a rule unmistakable. Rigidity, complete and universal, over the whole abdomen, is enough in itself. More important, because a few hours earlier in onset is the "expression" of the abdomen when it moves. For, contrary to the usual teaching, the peritonitic abdomen is *not* always motionless except in late cases. The movement, however slight, is characteristic.

It is diagnostic in most cases before one puts a hand on the abdomen. A hand on the chest and an eye on the abdomen is the best procedure. In a normal patient the abdomen comes out when the chest comes out (except for the first three or four respiratory movements, which should be ignored because all patients breathe self-consciously when first exposed). If after the first few breaths the abdomen goes in when the chest comes out, then the patient has a diffuse leak, will be found on palpation to have complete rigidity, and on laparotomy to have general peritonitis. It is a most important sign because a perforation may be accompanied by a low pulse-rate (44-48), and when this is combined with a normal temperature and false abdominal movements, it is as though the forces of Nature were conspiring to deceive the unwary diagnostician. It must be distinguished from the "morphinised" abdomen in which the movements are slight but in the normal direction. Moreover, there is a further refinement. If a transverse crease half an inch above the umbilicus is seen in an abdomen which has the reverse movement described above—or no movement at all, then the patient is likely to have a perforated duodenal or gastric ulcer. If, on the other hand, there is a transverse motionless axis about two inches below the umbilicus round which the abdomen "rocks"—i.e., the wall goes in below this axis and out above it—then the trouble is probably in the appendix, which is leaking mainly into the pelvis and less so towards the upper abdomen.

Owing to duodenal leakings coursing down over the right iliac fossa, duodenal perforations and ruptured appendixes are often identical in abdominal "expression" and rigidity. Vomiting is against gastric or duodenal ulcer and in favour of appendicitis. High temperature early is against both. But since diffuse rigidity tells us that a suprapubic drain will be required, a useful plan is to make a small suprapubic incision first and see what kind of fluid escapes. Pus which smells suggests appendicitis; pus without smell suggests a perforated gastric or duodenal ulcer; blood, an ectopic gestation, or pancreatitis. The next step is to stop the leak. Duodenal and gastric ulcers can nearly always be felt before they are seen, and the bubbles and turbid fluid will lead to the right direction. The ulcer should be boldly inverted, going through all coats with, for choice, floss silk. The second row of inverting sutures can be and should be catgut.

Drainage.

If the lesion is appendicitis the appendix should be removed, the stump inverted, and suprapubic drainage provided. This may be of glass or rubber. If of glass, which I prefer, it should be long rather than wide, and should settle down firmly in the pouch of Douglas so that its deep end cannot be moved by pushing the superficial end backwards, forwards, or from side to side. The feel of a "set" suprapubic tube is characteristic, and it will not be displaced by the patient's movements. Care should be taken that there is not a coil of small intestine between the tube and the rectovesical pouch. The average time to leave it in is 1½ to 2 days, but if any doubt exists a smaller rubber tube should be pushed down the glass tube *before* removing the latter, and in any case the tube should be rotated round its own axis within 24 hours to prevent omentum growing into the holes.

It is the practice of many surgeons to sew up these cases without drainage. Personally, I have never seen a suprapubic tube—properly managed—do any harm, and I believe that occasionally a case can be saved through providing drainage. Speed is an important factor in these operations.

The treatment of the extravasated contents and turbid fluid or pus has been much discussed. Most surgeons are now of opinion that it should not be wiped or washed. Lymph should not be picked off; it is protective. The function of the peritoneum is, in fact, to have peritonitis if necessary. Incidentally the use of packs in diffuse peritonitis is to be deprecated. They waste time and they rub the peritoneum, both things to be avoided.

The Fowler Position.

Suprapubic drainage is based on the fact that while we cannot drain the whole peritoneum we can at least put a tube into a place towards which we can coax the fluid to run by the position of the patient. This is the basic idea of the Fowler position. No excuse about the patient having "just slipped down" should be accepted. The angle should not be extreme but should be constant; there are many methods for maintaining the position. I used at one time pieces of wood triangular in section and the length of the width of a bed. The three sides of the triangle were *unequal*, so that one side could always be found to match the patient's thigh. One of these was put underneath the mattress and fixed. The aim is to produce by this or another method combined with a back-rest a large V into which the patient sits. I gather from the angle at which Murphy bends the rectal tube that the angle preferred by him is an exaggeration of the Fowler position. Experiments on the cadaver suggest that an angle of 45 degrees is enough to drain the whole of the peritoneal cavity; but this may not be applicable to the living. The patient should be put in the Fowler position while waiting for operation. Further, when he has to be moved to a home or hospital an ordinary motor-car is better than an ambulance because he cannot lie down in it.

After operation the patient's whole lymphatic system should be flushed with fluid in order to help the excretion of the toxins through the peritoneum. Rectal salines by the continuous method or by repeated injection are the most valuable. These can be supplemented or replaced, if the rectum is intolerant, by subcutaneous salines into the chest, rather than the thighs, which are too near the drainage-tube and liable to suppurate. As much fluid as possible should be given short of waterlogging the patient, and plenty of fluid may be given by the mouth even if the patient vomits.

Purgatives.

Purgatives after operation are open to discussion, but I always give 3 gr. of calomel 24 hours after operation—all in one dose so that if the patient vomits it can be given again without working out minute fractions. This is followed, in rapid succession until the bowels act, by mist. alb., a turpentine enema, pituitary extract, and eserine. The two latter seem to act on different types of cases, but it is difficult to prophesy.

My object in giving purgatives is not that I think people recover from peritonitis by having their bowels moved, but, first, because any distension hampers chest movements and increases the liability to bronchitis, and, secondly, because I want to know early if the patient is going to have post-operative paresis of intestines or not. An enterostomy may save him on the third day, but will probably be credited with having killed him if done on the fourth day. Lastly, I believe if the bowels are kept mildly wriggling for a few days after operation it prevents a thin film of lymph attaching one piece of gut to another from becoming a permanent organic adhesion and thus causing obstruction in a week or two.

Special Cases.

With regard to special cases, the question of doing a gastro-enterostomy at the time of perforation of an ulcer can only be decided by experience. Those surgeons who always do it appear to me to be wrong, and those who never do it equally wrong. It depends on a rapid summation of the following facts. If the number of years' history of ulcer is large, a gastro-enterostomy is indicated since mere suture is not likely to cure. If the number of hours since perforation is large, a gastro-enterostomy is not indicated since the toxæmia is great and operation should be as short as possible. If the number of minutes it takes the particular surgeon to do it is large, a gastro-enterostomy is not indicated. The fourth factor concerns the degree of stenosis produced by inverting the ulcer. This, I would point out, is never so extreme as one would think, from the peritoneal view of the pylorus or duodenum, and is only occasionally, by itself, an imperative indication for a gastro-enterostomy at the time of perforation.

Remote complications are, of course, bronchitis, pleurisy, and above all subphrenic abscess. Localised abscesses must be looked for as hard tender spots, and should be opened. The later they appear the safer it is to wait until they are localised.

Another complication which may supervene from 10 days onwards is a band forming as a result of the infection in the peritoneum. Persistent vomiting with a rhythmic pain and painless intervals is the best sign of this condition. Rarely have I noticed visible peristalsis under 11 days. The site of the band is fairly constant—it ties down the terminal ileum about two feet from the ileo-cæcal valve, and is due to this coil lying in the pelvis, the last part of the peritoneum to be freed from infection and, moreover, the site of the drain. The adhesion can usually be flicked off with a finger, and if operation is performed early nothing more need be done.

Conclusion.

It should be remembered that the four factors—early and quick operation, suprapubic drainage, Fowler position, and the administration of salines—have altered during the last 20 years the mortality of general peritonitis from over 80 per cent. to less than 20 per cent.

FRANK JEANS, M.A., M.B., B.C. Camb.,
F.R.C.S. Eng.,
Surgeon, Liverpool Royal Infirmary.

SHENLEY MENTAL HOSPITAL.—A new mental hospital for the County of Middlesex is to be erected at Shenley. It is to be on a modified villa system and will accommodate 2000 patients. In addition to the villas there will be enclosed buildings for 500 patients who are unfit to associate with the better type, and four buildings for about 270 sick and infirm.

PRESERVATIVES IN FOOD.

BY REGINALD DUDFIELD, O.B.E., M.B., D.P.H.,
MEDICAL OFFICER OF HEALTH, PADDINGTON.

THE communications which have appeared in the daily press since the issue of the Draft Regulations relating to the use of preservatives and colouring matters in foods make it desirable to inquire whether there be any statistical evidence indicating that harm has resulted from the use of what may be termed medicated foods. Many who have studied the question as a whole have strong suspicions that the use of chemical preservatives not only introduces risks of general accumulations of drugs in the system but also so interferes with the processes of digestion resulting in irritation of the intestinal mucous membranes, due to the presence in the digestive tube of foods which are not completely digested; these are then passed to lower parts of the tube not physiologically fitted to deal with foodstuffs in that condition.

It seems certain on first inspection that indications of increasing morbidity of the digestive tract—and more especially of the digestive tube—are to be found in the table of fatal cases of peritonitis, of gastric and duodenal ulcers, and of perityphlitis and appendicitis observed at Guy's Hospital during the 40 years 1880–1919.[1] Comparing the deaths of the first quinquennium (1880–84), when there was not a single death from either gastric or duodenal ulcer, with those of the last (1915–19), the latter show an increase of 168 per cent.

If the "irritation" theory of cancer, using that term in its loosest sense, be accepted, the mortality rates from cancer should yield at least a suggestion of the ill-effects of medicated foods, supposing that such medication interferes with digestion. The mean rates (Table I.) for the six decennia, ending 1910, have been taken from the Supplement to the Seventy-fifth Annual Report of the Registrar-General (Pt. III., p. ccviii.). The index numbers for the total (persons) mortality rates are shown in Table II.

TABLE I.—*Cancer: Annual Mortality per Million.*

	P.	M.	F.
1851–60 ..	326 ..	207 ..	440
1861–70 ..	396 ..	255 ..	522
1871–80 ..	484 ..	333 ..	619
1881–90 ..	610 ..	465 ..	739
1891–1900	767 ..	639 ..	882
1901–10 ..	867 ..	784 ..	942

P. = Persons. M. = Males. F. = Females.

TABLE II.—*Index Numbers: Persons.*

1851–60–100 : 1861–70–121 : 1871–80–148
1881–90–187 : 1891–1900–235 : 1901–10–266.

During the second and third decennia the increases in the mortality were 21 and 27 per cent., but in the fourth (1881–90) there was a sudden rise to 39 per cent.—the increase being taken by differencing each successive pairs of numbers. The use of drugs as preservatives of foods began somewhere between 1880 and 1885, and the two sets of figures here given show increases in morbidity (in the one case) and in mortality (in the other) roughly coinciding with the inception of the practice.

The earliest distribution of deaths from cancer according to the sites of the disease appears to have been made in 1901. At any rate, search for tables of distribution by sites, made in the Supplements to the Annual Reports of the Registrar-General, has led to the finding of two decennial tables only, one for 1901–10[2] and the other for 1911–20.[3] In the former decennium there were 309,141 deaths from cancer—127,807 of males and 181,334 of females—and in the latter 400,374 deaths—175,871 of males and 224,503 of females. The numbers in the second decennium (1911–20) show increases of 23 per cent. for persons, 38 for males and 24 for females.

[1] Proc. Roy. Soc. Med. (Section of Medicine), xvi., 45.
[2] Ann. Rept., 1910, p. lxii.
[3] Ibid., 1921, p. 62.

The deaths from cancer of the intestinal tube during the two decennia were as given in Table III. The numbers recorded during the second period show the increases (per cent.) over those for the first given in Table IV. It will be seen that in all instances the proportional increases were greater than those noted for the total mortality from cancer. These figures naturally suggest that the proportions of the deaths from cancer situated in the intestinal tube, expressed as percentages of the total numbers of deaths from cancer, have increased. The actual changes are shown in Table V. Table V. can be extended to 1922, the last year for which any statistics are available.

(1) Stomach. (2) Intestine. (3) Rectum.

The foregoing statistics indicate very clearly that since 1901 there has been a distinct increase in the mortality due to cancer of the intestinal tube and that the deaths due to cancer in those parts have increased proportionately more than the general mortality from this disease. The statistics submitted—admittedly incomplete—do appear to support the conclusions of the Departmental Committee as to the necessity of regulating the use of preservatives in foods. Indeed, the figures may be said to point to the desirableness of entirely prohibiting the use of drugs as preservatives.

A HOSPITAL AT HAYWARDS HEATH.—At the annual meeting of the governors of the King Edward VII. Memorial Eliot Hospital, Haywards Heath, on Feb. 19th, it was announced that the governors had decided to purchase the field adjoining the institution for £2000, and that Mr. and Mrs. S. L. Powell had given half of the required sum. It was explained that more room was urgently needed at the hospital, and the governors had realised the necessity of a nurses' home. Mr. Powell was re-elected president. During 1924 305 cases were treated in the hospital, an increase of 31 compared with the year 1923; 167 operations were performed and 119 accident cases admitted, increases of 11 and 9 respectively; 372 treatments had been effected in the X ray department and 319 photographs taken, and in the massage department 3514 treatments had been made. The accounts showed a balance in hand of £100 5*s.* 5*d.* on the year's working.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.[*]

(Continued from p. 679.)

EVIDENCE OF THE NATIONAL CONFERENCE OF INDUSTRIAL ASSURANCE APPROVED SOCIETIES.

(App. VI., 1 and 2.) The societies associated with the National Conference in the administration of National Health Insurance include, amongst others, the Liverpool Victoria, the National Amalgamated, the Royal Liver, and the Prudential Approved Societies. The number of insured persons who are members of the associated societies is over 6½ millions, of whom about 3½ millions are men and 3 millions women.

Home Service.

(App. VI., 5–8.) The membership of these societies consists in the main of those persons not previously associated with friendly societies. The benefits are paid and the contribution cards distributed and collected by means of the agency staffs of the various societies within the Conference, constituting an organisation which effectively covers practically every town and village in the United Kingdom. It is claimed for this "home service" that it is of great assistance to the insured persons, who are kept informed as to their position in insurance.

Getting the Act Started.

Evidence on behalf of the Conference was given by Sir Thomas Neill, Mr. E. F. Spurgeon, and Mr. E. T. Palmer. (Q. 4132.) They said that at the outset the Government of the day made an appeal to the Industrial societies to assist in making the National Health Insurance Act effective, and that it was generally conceded that but for that assistance the Act might have broken down at the time of its inception, having regard to the contentious atmosphere in which it was born.

(Q. 4436.) Competition amongst the Industrial group in the sense of trying to take each other's members, or to take members from other societies, is very much deprecated by the society managers.

Democratic Control.

(Q. 4442–4743.) An inquiry as to how societies in this group give effect to the requirements of the Act that Approved Societies should be under the absolute control of their members led to a lengthy examination on this question. Sir Thomas Neill contended that societies were so hedged round with regulations that they were left with little discretionary control. He agreed, however, on examination that there were many matters upon which managerial decisions must be taken in regard to which the members might exercise control if this were practicable.

The provisions in the rules enabling members to turn out the Committee of Management if they were dissatisfied contain the necessary elements of control by the members. If they did not turn up in large numbers at the meetings this seemed to betoken satisfaction on their part. In the National Amalgamated, 50 members, including the Committee of Management, formed a quorum, although the total membership of the society was 2,000,000. Special district meetings might be called to express dissatisfaction. In this case the quorum required by some rules is one-third of the members in the district. This led to the following interesting questions :—

---

[*] In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247–8); The Provision of Medical Benefit (Feb. 7th, pp. 301–3; Feb. 14th, pp. 355–6; Feb. 21st, pp. 403–5); Financial Provisions of the Act (Feb. 28th, pp. 454–7); Medical Certification and the Regional Medical Staff (March 7th, pp. 508–9); The Approved Societies and the Money Benefits (March 14th, pp. 564–5; March 21st, pp. 623–4); Evidence of the Hearts of Oak Society (March 28th, pp. 677–9).

References to the official statement which has been issued as an appendix in four sections are given thus; Section A. para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

> (Q. 4724–5.) When it comes to a matter of policy which is perhaps critical of the management, and we look at what is . . . a critical part of the machinery whereby insured persons give effect to their control of the Society, you require a quorum not of 50, but a quorum in Manchester of 21,000, in Birmingham of 17,000, in Lancashire of 30,000, and all the rest of it. It is a physical impossibility, is it not ?—It is.
>
> Q. So that the machinery for self-government breaks down there ?—Evidently it does.

Spreading the Insurance Risk.

(Q. 4934–7, 4990.) The witnesses thought that the societies should not suffer by the segregation of people employed in hazardous occupations. Combinations of smaller societies seemed desirable and a group with 100,000 members was probably necessary to get a fair average of sickness experience. (App. VI., 14.) The Conference were of opinion that a scheme ought to be devised under which the Approved Societies should absorb the whole of the Deposit Contributor class.

Married Women.

(Q. 5098. App. VI., 15, 16.) Insured women on marriage should be allowed to accept a bonus and terminate their contract of insurance. There was no particular demand for this from the women themselves, but the present insurance provisions were inconvenient and wasteful in administration.

Medical Benefit.

(App. VI., 17–19.) The Conference recommended that attendance at confinements, if so required by the insured person, and at illnesses arising therefrom, be included in the contract of service of insurance practitioners, a prescribed sum for such service being paid to the practitioner from the maternity benefit due to the insured person from his or her society. Apart from this and possibly (Q. 5118) grant of medical attendance to the wives of insured members, no general extension of medical benefit was suggested, but in the event of any material change in the character or cost of medical benefit being recommended to the Royal Commission, the Conference asked to be allowed to submit its views thereon.

A Fair Run for the Panel Doctor.

On the subject of the medical service for the insured, Sir Thomas Neill said that he did not wish to make any general criticism.

> (Q. 5121.) Even in the case of dignitaries of the Church and elsewhere you find there is a great deal of attention drawn to the wrongdoings of individuals. It is the same with medical service. There have no doubt been quite a lot of men who have had no regard to their obligations, but I think the medical profession and the Insurance Committees are dealing with this.

The medical service has not had a chance to function peacefully until 6 or 12 months ago, when the last arrangement was made with the medical profession.

> I do not think we have had a fair run with the present panel practice in peace and quietness to see really what it will do under these new regulations, and I would not be inclined to advocate it being extended for the present.

Specialist Services.

(Q. 5227–33.) The witness deprecated extensions in the way of specialist services at the present time, though he thought that in a few years the "top of the profession" should be available "for everybody."

Dental Benefit.

(App. VI., 22.) The Conference accepted the view "so widely held" that a measure of dental treatment should be available to all members of Approved Societies. The scale of fees and the character of the dental service should be negotiated by a special committee representing the Ministry and Approved Societies on the one hand and the dental profession on the other. It was suggested that $\frac{1}{2}d.$ out of every contribution should be credited to a central fund, and that this fund, after meeting certain charges, should be distributed to societies for the purpose of providing as a first charge dental treatment on a uniform basis throughout the country. This proposal appears from the evidence to be merely a means of avoiding a pooling of any part of the societies' surpluses. (Q. 5302.) The witnesses said that while they objected to raiding surpluses, there was not the same objection to anticipating a surplus. Sir Alfred Watson asked :—

> (Q. 5291.) I want to know why all that elaborate financial structure is required, seeing that all you are after, so far as my ability enables me to judge, is a clause or series of clauses in the Act creating the right to statutory dental benefit, and imposing on all societies the obligation to administer it and to pay for it out of their funds ?

The answer to this question was elaborate but a little unconvincing. As to the extent of the benefit, it was suggested in the evidence that $\frac{1}{2}d.$ per contribution would provide a sufficient fund to pay bills in full up to the first £ and 50 per cent. of the remainder.

(Q. 5398–9.) The witnesses objected to the proposed dental service being handed over to the local health authority. Sir Thomas Neill said :—

> As far as these people who are specially paying for this treatment are concerned, I hope this Royal Commission will not suggest that they should be dealt with in the same way as the tuberculous insured who are not being properly attended to ; nor in the same way as the blind people who should be provided for under the Blind Persons Act, and who are not being properly attended to.

Insurance Committees.

(Q. 5448–9.) The Conference which the witnesses represented are in favour of maintaining Insurance Committees as at present constituted, and with their existing duties, but they were not in favour of entrusting them with additional duties.

EVIDENCE OF THE MANCHESTER UNITY APPROVED SOCIETY.

Evidence was given on behalf of this society by Mr. Edwin Heather.

(App. VII., 4–23.) The Manchester Unity Friendly Society was established in 1810. This Approved Society is the largest of the affiliated orders administering National Health Insurance. The Manchester Unity is governed by the members themselves formed into branches called Lodges. Every member has an opportunity of taking part in the administration of the affairs of Lodge, District, and Order. He may pass through the various offices of Lodge and District, he may be a deputy to the Annual Movable Conference, and has opportunities of attaining the highest position in the society. The society claim that the system creates self-dependence, builds up character, teaches mutual responsibility, fosters the cultivation of fraternal principles, and is therefore a great national asset. It is working well and efficiently. (Q. 5466–8.) There are 3500 Lodges in the society and the average membership for each Lodge is about 250.

(Q. 5497.) The number of members who pay for extra benefits on the private side as well as being State insured is nearly half a million. (Q. 5525.) Those who are State insured only do not display much interest in the work. They have joined the Manchester Unity just as they might have gone to an Insurance Company and taken out a policy.

(Q. 5486–7.) The witness said on behalf of the Board of Directors that they were treated with every consideration by the Ministry of Health, and he dissociated himself from the opinion implied by the words of the late Grand Master at the last annual meeting, when he said "We do not intend to become mere vassals of arrogant bureaucracy."

The Value of Voluntary Thrift.

(Q. 5578–91.) The witness emphasised the value of voluntary thrift. For this reason he deprecated any increase of the cash benefits under the National Health Insurance scheme. The society wished to provide for this by voluntary thrift because they thought it a valuable thing to the nation as a whole. (Q. 5759.) The compulsory character of National Health Insurance explained the lack of interest which members showed in the working of the scheme.

The Importance of Non-Cash Benefits.

(App. VII., 49.) The society state that there is a growing feeling that future surplus should be used in a greater degree for the provision of non-cash benefits rather than be applied to an additional few shillings per week as an additional sickness benefit which does not to any degree reflect itself in the restoration to good health.

Extension of Panel Service.

(Q. 5794-7.) The witness's personal opinion was that the treatment given by panel doctors is, generally speaking, of a satisfactory nature and that it compares favourably with that given to members of the society before the days of National Health Insurance.

(App. VII., 59-61.) The Manchester Unity are of opinion that the panel system should be continued and extended to include consultant and specialist services, the additional cost being met out of present contributions. (Q. 5831.) Until full arrangements with specialists are possible, it was suggested that these services should be arranged through the voluntary hospitals on a special scale of fees to be paid to the hospital.

Dental Treatment.

(App. VII., 53-8.) There is a considerable demand for this benefit and the society suggested that it should be one of the statutory benefits of the Act. Defective teeth are a predisposing cause of many diseases, and the provision of dental treatment would tend to lessen the other claims on the society.

(Q. 5779, 5800.) Though in general opposed to pooling of surpluses, the Manchester Unity for the purpose of this particular benefit agree to the principle of the strong helping the weak. If the benefit were not made a statutory one, the witness said they were prepared to make it uniform throughout their own society by means of a central fund to which all the Lodges would contribute.

Marriage Bonus.

(Q. 5846.) The Manchester Unity are opposed to a marriage bonus, mainly on the ground that if once conceded it would be difficult to refuse a bonus to other persons going out of insurance.

(App. VII., 63.) They propose that one year's free insurance should be granted to married women on ceasing insurable employment.

Sickness Benefit from the First Day.

(Q. 5894.) The society recommend that sickness benefit should be paid from the first day of incapacity instead of, as at present, the fourth day. This is done on the private side and causes no difficulty.

> We recognise that it would, in the first instance, be an increased charge on the benefit fund, but we think it would subsequently mean a reduction of the charges for sickness benefit as it would prevent many cases of prolonged illness.

NEW HOSPITAL FOR DARLINGTON.—The pressure upon Darlington General Hospital (107 beds) has become so severe that a new War Memorial Hospital is to be built upon a site of 17 acres. There will be 229 beds and the cost will be £185,000. The complete scheme, to be carried out eventually at a cost of £232,000, will provide for 299 beds.

HOSPITAL BEDS FROM "SILVER PAPER."—It is stated that four beds in London hospitals have recently been endowed by the sale of the tinfoil or "silver paper" used for putting up tea, chocolate, tobacco, and cigarettes. It is understood that it is used for making solder, and 85 tons of it have realised £1250. The Ancient Order of Druids Tinfoil Fund, through its lodges all over the country, collects the paper and gives the proceeds to the local and London hospitals.

MEDICINE AND THE LAW.

THE FAILURE OF A CLAIM ALLEGING NEGLIGENCE.

THE Lord Chief Justice, with a special jury, recently tried an action in which Mr. W. Gray and his wife sued Dr. W. E. Peacock for damages for alleged negligence in treating Mrs. Gray during her confinement, Dr. Peacock counter-claiming for his fees. After three days' trial a verdict was found for Dr. Peacock and judgment was entered for him on the claim and the counter-claim, with costs.

On March 26th, 1923, Mrs. Gray, who had engaged Dr. Peacock to attend her in her confinement, was stated to have had signs of labour at 2 A.M., and felt the first real labour pains at 8 A.M., but to have experienced no serious pains during the day. Dr. Peacock was present at 10 A.M. and at 7 P.M., and at 8.30 P.M. attended in response to a telephone call, the pains having become serious at 8 P.M. With reference to the delivery, which was completed at 9.50, a question arose at the trial as to whether Dr. Peacock's offer "to help her" was understood by Mr. and Mrs. Gray to refer to the use of the forceps; but in any case he administered chloroform and used forceps, with the result that a male child was born, who is now strong and healthy. Rupture of the perineum took place, and Mr. Gray went out and obtained gut and needles for Dr. Peacock's use, as he was without them. It was stated that the adequacy of the gut was questioned by Dr. Peacock before he used it. The after-birth was left and removed under chloroform at 8 o'clock next morning by Dr. Peacock and Mr. R. M. Rowe. On March 31st the stitches gave way, and were not renewed until May 17th, when the patient had been taken to a nursing home, where she was operated on by Dr. F. J. McCann and Dr. E. Burnet. The plaintiffs' claim included £220 for expenses of treatment and convalescence thus incurred, and it was agreed that the counter-claim for medical fees should abide the issue on the claim. The principal points relied on in support of the claim, as to which interesting expert evidence was given, were the use of mechanical means of delivery at the stage at which they were employed, delay in removing the after-birth, and the suture of the perineum and its failure, including alleged undue delay in attending to the case after the stitches had given way.

Dr. Burnet said in evidence that an after-birth should never be left without removal for more than an hour, and that in no circumstances should the mother be left until it had come away. The medical attendant should come prepared for all contingencies such as a tear. In the case of a perineal tear of the third degree, a reparative operation should be performed immediately after the conclusion of the third stage of labour. In his opinion, there was no justification for the damage done or for leaving it without repair. He ascribed Mrs. Gray's condition to precipitancy in delivery, but not to delay in removing the after-birth. The fact, however, that the after-birth came away safely next morning did not justify the fact of its having been left. He had not himself attended a confinement for about ten years. Dr. McCann stated that when he performed the operation on Mrs. Gray on May 17th the matter was urgent. He was inclined to the opinion that it might have been performed on May 11th when he first saw her, but could not say positively that it might have been performed earlier. It seemed to him extraordinary that with severe pains not before 8 P.M. the forceps should have been used at 9.30. He agreed, in cross-examination, that Dr. Peacock's record of long practice without the loss of a child and with no case of sepsis was a fine one, and that such a man on the spot should be the best judge as to the use of forceps. He admitted that though, personally, he held the opinion that where the stitches in a perineal tear had given way an operation should take place as soon as possible, other medical men thought that it should be delayed, even for three months. A practitioner acting on the latter view would not be failing to take reasonable care. Mrs. Gray's condition was due, in his opinion, to the use of the forceps, but he was not prepared to say merely because the forceps had been used that its use was improper. Dr. W. E. Falconar expressed the opinion that if Mrs. Gray's own account of her condition were assumed to be true there was no such exhaustion on her part as would justify the use of the forceps.

For the defence Mr. A. W. Bourne gave evidence, and in answer to Lord Hewart said that the use of the forceps must depend upon the patient's symptoms and the condition of the child, and not on "the hands of the clock." Dr. L. Phillips expressed agreement with Dr. Bourne's evidence. Mr. V. Bonney, who had known Dr. Peacock for 20 years, gave evidence that it was not improper to use forceps an hour after the beginning of the second stage of labour. In a woman who had had nothing to eat all day exhaustion might result in nature refusing to do its work. Perineal tears did not prove precipitancy, and proper use of the forceps might minimise it. If first sutures broke down he always waited six months before a further operation, in order to avoid sepsis. The defendant, Dr. Peacock, said that he had been for 30 years in practice without any case of sepsis or loss of a child. He described Mrs. Gray's condition before and at her confinement. He stated that owing to her exhausted state he used forceps, and owing to her exhaustion and the danger of sepsis he left the after-birth unremoved. He had no reason to hurry the confinement and did not do so. He postponed repairing the broken-down suture because it was his practice to do so for at least three months. He was still satisfied with the result of Mrs. Gray's confinement. Nurse E. Ferry said that Mrs. Gray was rather frail and was very nervous before her confinement; on the day on which it took place she had been unable to take food; it was a very difficult birth and Mrs. Gray was exhausted. Mr. Rowe, who saw Mrs. Gray on the morning after her confinement, considered that events had justified Dr. Peacock's treatment of the case. When summing up the evidence, after counsel had addressed the jury, Lord Hewart said the question for the jury was whether or not Dr. Peacock had used reasonable care and was justified in using forceps, and if not whether Mrs. Gray's injuries were the result of his use of instruments and of his negligence. The jury, as has been stated, found a verdict for the defendant, who is to be congratulated upon a just verdict after a full and fair setting out of the arguments. The defence was conducted by Messrs. Hempsons on behalf of the Medical Defence Union.

PARIS.

(From our own Correspondent.)

National Health Insurance Bill.

The proposed Bill dealing with national health insurance (les assurances sociales) is causing lively apprehension for the future of medicine among the medical profession of France. Dr. Weiss, dean of the Medical Faculty of Strasburg, recently read a communication to the Academy of Medicine in which he described the results of the working of the system in Alsace and in Lorraine in so far as it affected the medical profession, showing how such apprehension was justified. In fact, Dr. Weiss held that the independence and the dignity of the doctor had been lowered, that the science of treatment had been debased, and that medical teaching had been compromised. The leader in the present movement against the system of health insurance is Dr. Balthazard, professor of forensic medicine at the Medical Faculty of Paris. He maintains that the proposed Bill, which is at the moment being investigated by the Senate through a Hygiene Commission, must be remodelled in such a way as to retain a certain proportion of the principles on which the reputation and high standing of present-day French medicine is based, and he is anxious that the Academy of Medicine should pass the following resolution: That, in order to avoid a set-back in medical progress, the law dealing with health insurance must respect the following principles, which are essential for the maintenance of the best traditions of French medical service, and which, if neglected, would preclude the profession from loyally upholding the law: 1. Free choice of doctor for the insured, and direct relationship between the doctor and the insured, without the interposition of clubs (caisses). 2. Absolute respect for medical secrecy. 3. Control of the insured to be in the hands of the clubs, the medical attendant acting solely in the interests of his patient. 4. Obligation on the part of the clubs to make use of the hospital organisation of towns which possess a medical faculty or a school of medicine, hospital fees being fixed by an arbitration commission.

Prophylaxis Against Tubercle.

Dr. Léon Bernard, professor of hygiene at the Faculty of Medicine of Paris, recently demonstrated before the Academy of Medicine the excellent results obtained in the prophylaxis against tubercle in young children by separating them from tuberculous parents and boarding them out (placement familial). The figures he quoted were based on five years' observation of children who had been kept free of the disease through the system of ante- and post-natal prophylaxis which he, along with Dr. Robert Debré and Dr. Marcel Lelong, had instigated and organised. Of 265 infants of tuberculous parentage who were removed from their families before any infection had taken place, all showed a period of retarded growth up to the age of 18 months and then became quite normal, both in regard to weight and powers of resisting infection. The resistance to the tubercle bacillus was particularly noticeable, for with one exception all the infants escaped later accidental infection. The mortality was relatively high in the first month of life, but after three months it was 5·7 per cent., a normal figure. Among 171 infants removed from a tuberculous milieu when already infected there was a certain amount of malnutrition during the first year, but at the end of 18 months body-weight and powers of resistance to infection were normal. The mortality from secondary tuberculosis was 7·6 per cent. Dr. Bernard also conducted an inquiry into the cases of infants who had either been refused boarding-out facilities or whose parents had refused to allow the separation. Out of 66 cases traced, 54—or 82 per cent.—had died, that is a mortality of 82 per cent. compared to 7·6 per cent. among boarded-out infants. These results show the prophylactic value of separation in combating tuberculosis where the infants are removed from a source of contagion.

An Accident with an Electric Iron.

Prof. Zimmern, of Paris, recently had to deal with a case where the patient had suffered severe injury through an accident arising out of the use of an ordinary domestic electric iron. The iron was connected to the house current of 220 volts. The victim, a woman, finding that the iron was not getting hot, took it up in her hand, and noticing that a screw was loose near the heel of the apparatus began to tighten it with her right hand, while with her left she grasped the ironing surface. The current was thus short-circuited through her body, and produced such a violent contraction of the flexor muscles of the forearm and of the elevating muscles of the shoulder that her left wrist was broken. In addition she sustained burns of the third degree on her fingers, and later she suffered intense pain in both shoulders, due apparently to injury to the nerves.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

A Berlin "Health Week."

HYGIENE propaganda on a large scale was recently carried out on behalf of the city authority in Berlin during the week from March 16th to the 21st. The "Health Week" was opened by a meeting in the town hall, where addresses were delivered by the mayor, the director of the municipal health office, and representatives of the medical faculty of the university and of the medical profession. A well-known hygienist, Prof. Drigalski, praised the work of the medical profession in the prophylaxis of epidemics and the improvement of the hygienic condition of the city. He stated that neither during the war nor afterwards had any appeal to the profession been made in vain, and that no other profession had done so much for the public welfare without remuneration as had the medical profession. During the week films on hygienic matters were shown in a great number of cinemas, and in every district of the town lectures were delivered by the district medical officers and other medical men on tuberculosis, infectious and venereal diseases, infant mortality, and analogous subjects. The lectures were attended by about 50,000 people. In the municipal schools the children were instructed by the teaching staff and by medical men on the importance of hygiene. Pamphlets were distributed free of charge throughout the city and the suburbs. The "Health Week" proved a success.

Meeting of Cancer Committee.

The Cancer Committee some time ago held a jubilee meeting together with the Berlin Medical Society. The meeting was honoured by the presence of the late President of the German Republic—his last attendance at a public meeting before his fatal illness. Lectures were delivered by Prof. Warburg on the metabolism of the cancer cell, and by Prof. Lubarsch on the history of cancer research during the past 25 years. Prof. Blumenthal, head of the cancer department of the Charité Hospital, spoke on the treatment of cancer by modern methods, mentioning that, apart from Rontgen rays and of radium, injections of thorium had proved successful. He suggested that he had been able to cultivate bacteria from cancer in human subjects. In 16 cases three different species of bacteria were found which on inoculation into animals produced new growths, which could be re-inoculated in animals of the same species and become ulcerous like cancer. To develop the growth, however, not only inoculation of the bacteria, but also addition of an irritant was necessary, infusorial earth having been chosen for that purpose.

A Wax Candle in the Bladder.

Before the Medical Society of Cologne Dr. Goldberg described the case of a patient who had introduced a small wax candle in the urethra. The candle unfortunately glided into the bladder, producing there hæmorrhagic purulent cystitis. After cystoscopy, to ascertain the presence and the position of the candle, Dr. Goldberg tried to remove it by a lithotriptor, but this proved impossible. He therefore made an injection of 50 g. of lukewarm benzine into the bladder, the result being that the wax was melted and could be drawn out together with the benzine by an evacuator. When the benzine had evaporated it was ascertained that the weight of the removed wax was equal to that of the candle, and that therefore no part of the candle had been left within the bladder.

Death from the Administration of X Rays.

The chief surgeon to a hospital in Dresden, his assistant surgeon, and a nurse were prosecuted recently on the allegation that they had caused the death of two women by the administration of X rays. The patients were suffering from cancer and they had applied the rays in high doses without using a safety filter. Severe burns were caused and death finally occurred. By post-mortem examination it was ascertained that the deaths had in fact been caused by the treatment. Expert evidence was given for the prosecution and for the defence. The court found a verdict of guilty of manslaughter by neglect. The assistant surgeon and the nurse were sentenced to two months' and one month's imprisonment respectively, being, however, allowed a postponement of the sentence upon bail. The chief surgeon of the hospital was fined severely, because, although not having been himself actively concerned in the treatment, he had neglected to supervise the work of his assistant and the nurse.

Responsibility of an Asylum.

A mentally afflicted man interned in an asylum begot a child with a nurse of the asylum. The nurse therefore brought an action for alimony against the patient and obtained a judgment for herself. The patient thereupon brought an action against the asylum to recover the costs, because they were responsible for not having sufficiently guarded him as was their duty. The court found against the asylum. The High Court of Justice, however, on appeal, cancelled the first judgment, stating that the asylum had neglected their duty by not selecting specially trustworthy nurses for a man who had been confined partly on account of his excessive sexual desires; on the other hand, it was decided that the patient had not totally lost his free-will by his mental disturbance. The asylum therefore had only to pay a part of the damages.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. E. T. Burton is placed on the retd. list with the rank of Surg. Capt.

ROYAL ARMY MEDICAL CORPS.

Maj.-Gen. T. W. Gibbard, K.H.S., late R.A.M.C., having attained the age for compulsory retirement, is placed on ret. pay.

Col. W. H. S. Nickerson, V.C., M.B., late R.A.M.C., to be Maj.-Gen., vice Maj.-Gen. T. W. Gibbard, K.H.S., to ret. pay.

Lt.-Col. V. J. Crawford, D.S.O., to be Col., vice Col. W. H. S. Nickerson, promoted.

Maj. G. H. J. Brown to be Lt.-Col., vice Lt.-Col. V. J. Crawford, promoted.

Capt. F. K. Escritt is restd. to the estabt. and relinquishes the local rank of Maj.

TERRITORIAL ARMY.

W. H. Gratrix to be Lt.

ROYAL AIR FORCE.

Flight Lt. J. C. Johnson relinquishes his temporary commission on ceasing to be employed.

ROYAL SUSSEX COUNTY HOSPITAL.—At the annual meeting of this large hospital at Brighton it was suggested that difficulties might arise in regard to the increasing number of motor casualty cases. During 1924 the casualties of all descriptions dealt with numbered 4208, as compared with 3832 in the preceding year. In addition, 1327 other cases were seen in the casualty department, an increase of 378, and 16,138 casualty dressings were done in the out-patients' department, an increase of 2203. It was explained that the great majority of the casualties arose from motoring accidents, particularly at week-ends, and with the continued increase of motors on the road the question was one which was causing grave concern to the governors. At the present moment it was believed that a ward for fractures only could be opened. In a fortnight in February this year there was a waiting list of 139, and of the 100 admissions 47 were emergencies and casualties. In-patients during 1924 numbered 3278 against 2588 in 1923, an increase of no fewer than 690. Brigadier-General D'Arcy C. Brownlow declared that the salaries they gave the nurses were inadequate in proportion to the great work they did for the hospitals.

Correspondence.

"Audi alteram partem."

THE BATEMAN FUND.

To the Editor of THE LANCET.

SIR,—The result of the Bateman Appeal is of such importance to the medical profession as a whole that, though I work abroad and am therefore beyond the verdicts of British juries, I send with pleasure a subscription.

As a callow house surgeon 25 years ago I nearly fell a victim to a jury ignorant of technical matters before whom a case had been stated incorrectly by a policeman on oath. I received the censure of the foreman of the jury, both on the conduct of the hospital and my own conduct, a censure which the surgical staff and the house committee of the institution immediately repudiated in the public press. I may add that, as I left the court-house speechless with rage, a man ranged up beside me and said, for my private information, that the foreman of the jury was, as a matter of fact, the person who had supplied the victim in question with the drink from which the fatal accident arose.

I have not forgotten the circumstances and, in enclosing my card, sign myself,

Yours faithfully,

Spain, March 20th, 1925. A VINDICTIVE SCOT.

HEALTH STATISTICS OF THE MERCANTILE MARINE.

To the Editor of THE LANCET.

SIR,—The interesting correspondence that you have recently published with reference to the health of the Mercantile Marine indicates that the progress that has been made both nationally and internationally during the last six years has not been fully appreciated.

Colonel Burke points to the conditions of seamen under the Merchant Shipping Acts in 1916, stating that "he is excluded from the benefit of free treatment." From 1920 until 1923 members of the Parliamentary Committee of the National Council made three endeavours to secure the passage of an amending Bill. This became the Merchant Shipping Amendment Act in 1923, and brings the treatment of seamen for venereal disease under the same conditions as other ailments. For the future, therefore, drugs will be available on every ship, together with such disinfectants as may be required by those who have exposed themselves to the risk of infection and are unable to visit a clinic before reaching the next port. The owners of the lines plying between the British and Scandinavian ports have for the last three years undertaken to distribute leaflets, giving the times and addresses of the free clinics in the ports at which their ships called.

Since 1918 the Office Internationale d'Hygiène Publique has had under consideration the question of securing continuous treatment for these diseases for seafarers of all nations. In 1920, at the International Labour Conference of the League of Nations at Genoa, the whole problem was discussed at a special meeting of the delegates, convened under the auspices of the National Council for Combating Venereal Diseases. As a result of this meeting, a set of resolutions was drawn up, adopted by the conference, and circulated to all participant Governments. They called for—

1. The provision of adequate facilities for the prevention and treatment of venereal diseases at all the principal ports.
2. The inclusion of venereal diseases among the conditions for which free drugs and treatment are provided for members of the Mercantile Marine.
3. The dissemination of appropriate information on the subject to seafarers, and especially to those at training establishments.
4. The provision of adequate facilities for recreation at all large ports under the administration of a joint organisation representative of owners and seafarers.

They desire, in addition, to call the special attention of the International Labour Organisation to the importance of recommendation No. 4 about facilities for recreation.

These resolutions were also transmitted to the Health Section of the League and stimulated general interest in the whole problem, assisting the Health Section of the League and the Office Internationale to secure support for the completion of the international arrangement relating to facilities to be afforded to merchant seamen for the treatment of venereal diseases.

The following countries have already signified their willingness to sign the agreement: Argentine, Canada,* Cuba, Denmark,* Finland, France,* Great Britain,* Greece, Italy,* Monaco, New Zealand,* Netherlands,* Peru, Roumania, Spain, Sweden,* Tunis, and Uruguay. Those marked with an asterisk have already opened free treatment centres, as has also the Government of Brazil.

With the coöperation of the Shipping Federation and of the Seafarers' Joint Council a special pamphlet entitled the Seafarers' Chart of Healthy Manhood, containing a list of over 200 free treatment centres in the principal ports of the world, which has been published by the National Council with the assistance of the Ministry of Health, is about to be distributed to the whole of the British Mercantile Marine.

The Union Internationale contre le Peril Venerien, established in conjunction with the League of Red Cross Societies, and on which 25 countries are represented, together with the Health and Labour Sections of the League of Nations, made the health of the seafarer one of their first considerations. In 1923 the Council of Direction appointed a Ports Committee, of which the representative of the National Council for Combating Venereal Diseases was appointed chairman. Arrangements are now in train to stimulate the practical application of the agreement by arranging for a small commission of two or three experts representing the Union Internationale to visit the principal trading ports. Shipping and seafaring interests in the different countries are being invited to coöperate with their National Social Hygiene or Anti-Venereal Disease organisation in raising funds to finance the undertaking.

It will be seen from the above that the National Council, in coöperation with the British Shipping Federation and the Seafarers' Joint Council, have kept the interests of the health of the British Mercantile Marine prominently in the foreground.

I am, Sir, yours faithfully,

S. NEVILLE ROLFE,
General Secretary, National Council for Combating Venereal Diseases.

102, Dean-street, London, W., March 30th, 1925.

To the Editor of THE LANCET.

SIR,—The letters of Dr. H. M. Hanschell and of Sir P. J. Michelli in your issue of to-day reinforce admirably, and with most practical illustration, the main plea in my letter of March 21st. In that letter I made no reference to the Port of London. I was taking it for granted that all who were interested in the venereally-diseased sailor were aware of the splendid work which has been, and is being, done by the Seamen's Hospital Society. That work is known and appreciated by all who sail the Seven Seas. What I appeal for might be translated as—"Let us have more work along similar lines at all other ports." Owing to the conformation of the Port of London, it is, as Sir P. Michelli says, practically impossible to have a treatment centre in every dock. Those at the Dreadnought Hospital and at the Albert Dock are handily situated; and I suggest no deficiency as far as the Port of London is concerned. My contention is that any large port which does not possess a treatment centre which is open all day and every day within the area of the docks or immediately adjacent, is making no attempt at the care of the seafarer who is the victim of V.D. For example, in the case of the Port of Manchester, the fact that in the neighbourhood—but by no means adjacent to the docks—there are at Salford Royal and at St. Luke's Hospitals V.D. treatment centres, is of little or no use to the sailor. These places are neither open all day nor every day. Most other ports are similarly situated—the sailor is not catered for.

When I referred to my ideal treatment centre being "exclusively for the use of sailors" I was thinking of it being actually within the dock boundaries. It would have expressed my idea better to have used the term "especially" rather than "exclusively," as I wished to indicate that the centre would not be for the use of the general population but for those whose work involved their presence inside the docks or who lived in the immediate vicinity.

Preventive treatment—in every sense of the term—is, I consider, essential in dealing with venereal diseases. The whole question is a public health one, and must be tackled along public health lines. I am aware of all that has been urged against this view, but that controversial aspect need not be discussed here. One would only point out to Dr. Hanschell that at the present time—as for centuries past—men are signed on who have risked infection, they are neither "cleansed nor injected," they proceed to sea, and a high proportion of them develop V.D. Owners, masters, crews, passengers, medical officers, all know it, and that the chance of such men developing disease is a very high one. Whether or not preventive treatment would increase the number of exposures is beside the point; it would assuredly reduce the number of infections. The fact that a man "agrees or confesses to a chance of developing V.D."—i.e., admits exposure to infection *and is treated on that*—practically ensures that chance vanishing. Preventive treatment efficiently applied and within the correct time does prevent the development of syphilis and gonorrhœa.

The certificate of prophylaxis which I mentioned in my last letter need not, of course, be attached to the man's papers. He might retain it himself. The former method was suggested to lessen the chances of the certificate getting lost, and the man suffering any unjust penalty on the grounds that he had neglected to avail himself of preventive treatment. Again one would express the hope that port authorities who have neglected to do so, will, in the immediate future, make arrangements for the prevention and treatment of V.D. in the areas administered by them.

I am, Sir, yours faithfully,
E. T. BURKE.
Manchester, March 28th, 1925.

MALARIAL TREATMENT OF GENERAL PARALYSIS OF THE INSANE.

ICE METHOD OF INOCULATION.

To the Editor of THE LANCET.

SIR,—The ideal and most practicable method of infecting general paralytics with tertian malaria fever consists in the subcutaneous injection of 1½ to 3 c.cm. of malaria-infested blood withdrawn from the vein of a patient suffering from the disease. The procedure is likely to be attended with success where the inoculation is carried out immediately and when the donor and recipient can be brought together.

The impracticability of employing infected mosquitoes owing to relapses in conveying infection to cases of G.P.I. and the difficulties encountered in the cultivation of *Plasmodium virax* outside the body beyond a definite length of time, have prevented many hospitals distant from a malaria-donor from adopting this method of treatment, and it is my purpose in this note to acquaint your readers of a method that has been devised and tried which will enable a patient residing in any part of the British Isles to acquire the disease irrespective of the distance between donor and recipient.

The technique of the method is easily carried out and was first described by Pötzl of Prague. Ten to 15 c.cm. of venous blood are withdrawn from a patient suffering from malaria fever and allowed to run into a sterile glass flask of 30 c.cm. capacity, containing 10 to 15 small glass sterile beads. The flask is closed with a sterile cork and the whole gently shaken for ten minutes, at the end of which time the blood becomes defibrinated and partially hæmolysed. The serum is then gently poured into a sterile test-tube, corked, and placed either in an ice-chest or a thermos flask containing ice at 0°C. The latter apparatus is convenient where it is required to send a sample of blood by train to some distant town or hospital. Blood has been sent in this way to London, Liverpool, Birmingham, and Cheadle (Cheshire).

My experience of this method of inoculation dates from Nov. 1st, 1924, since when a series of 12 cases have been treated. The amount of blood injected varied from 2 to 6 c.cm. and was given to the patient by the subcutaneous or intramuscular route. Up to the time of writing I have been able faithfully to reproduce the fever in ten cases with specimens of blood kept at 0° C. outside the body for a period up to 66 hours. Again, I have been able to stain tertian parasites in iced defibrinated blood aged 7 days.—I am, Sir, yours faithfully,

J. D. SILVERSTON, M.B., B.S. Durh.,
Senior Assistant M.O., County Mental Hospital,
Whittingham, Preston.

THE TREATMENT OF PULPLESS TEETH.

To the Editor of THE LANCET.

SIR,—This letter is occasioned by the leading article in THE LANCET of Feb. 7th on this subject.

There are two minor points to which I take partial exception. These relate to (1) the interpretation of the results of the bacteriological examination, and (2) the economic feasibility of such an examination. In the first place, you write: "The ideal treatment should logically include cultures from the root canal to ascertain when they were free from infection . . ." This statement implies that it is possible to ascertain when root canal (periapical) infection has been eliminated. On the contrary, infection may be present in spite of a negative culture, which consequently does not *ipso facto* give the dentist warrant to proceed to the definitive occlusion of the canals. A positive culture, however, means emphatically that the canals are not yet ready for filling. In this lies the chief usefulness of bacteriological examinations in root canal work.

Further on the economic aspect of these examinations is brought up. "As a practical addition to private practice it is scarcely feasible, for it would add so much to the cost and length of treatment as to make it prohibitive except to a favoured few." This I do not believe is necessarily true, as will appear in what follows. For a number of years bacteriological, as well as roentgenographic, control of root canal technique has been routinely pursued in the clinics of the Dental School of the University of Pennsylvania. Our practice is first to have a smear made on a glass slide from a dressing which has been sealed in the tooth. This is not done until the clinical experience of the operator indicates that the root canals are ready for filling. This smear is stained and examined with an oil-immersion lens. If bacteria or extremely large numbers of polymorphonuclears are found the conclusion is drawn that infection persists. Treatment may be continued or recourse may be had to apical curettage, root amputation, or extraction. If bacteria are not found and if polymorphonuclears are few or absent, then a culture is taken. If this be negative 48 hours later, and if no clinical contra-indications appear in the meantime, the canals are definitively filled.

When I last went over the records 937 cultures had been made. Before each there had been a direct microscopic examination of a smear made from the canal dressing, which microscopic examination had failed to reveal bacteria. This negative result was confirmed by 467 of the cultures, and contradicted by 470 of the cultures. In other words, of two negative microscopic examinations, one will be confirmed and the other contradicted culturally.

These results also emphasise another point which is in consonance with the spirit of your article. Over one-half of the root canals, clinically deemed ready for filling, showed persistence of infection. This result by stressing the unreliability of clinical criteria alone stresses the value of bacteriological checks. Assuming for the sake of argument that a cultural examination is not generally feasible on economic considerations, this objection cannot hold for the direct microscopic examination of a stained smear. The time required for this is at a maximum five minutes. It is done while the patient is in the chair, and in case of a positive result one can at once return to the treatment. Not only is the time, but what is at least quite as important, the *continuity* of the treatment is saved.

Wherever cultural examination is for any reason not made, this direct microscopic examination alone may be used, and it has proved to be an appreciable improvement over current visual and olfactory tests. Many times a dressing, which grossly appears inoffensive, will show microscopically the incontestable presence of bacteria. This direct microscopic control in root canal work reaches its maximum of usefulness when dichloramin-T or some other lymphogogue is used in the treatment.

I am, Sir, yours faithfully,
JOSEPH L. T. APPLETON, Jun.

The Thomas W. Evans Museum and Dental Institute,
School of Dentistry, University of Pennsylvania,

THE HOSPITAL POLICY OF THE BRITISH MEDICAL ASSOCIATION.

To the Editor of THE LANCET.

SIR,—A meeting of the consultant physicians and surgeons attending the voluntary hospitals of Birmingham was held on March 20th. The meeting was called for the purpose of nominating members for the Local Hospital Committee of the British Medical Association, and for the purpose of discussing the hospital policy of the B.M.A. At this meeting the following resolution was carried unanimously :—

> That, taking into consideration the importance of medical education and the fact that the large teaching hospitals are specially organised and staffed for such work, this meeting is of the opinion that in the scheme of hospital policy of the British Medical Association these hospitals should be put in a class by themselves.

I am, Sir, yours faithfully,

Birmingham, March 26th, 1925. JAS. M. SMELLIE.

THE USE OF RADIUM EMANATION.

To the Editor of THE LANCET.

SIR,—It has recently been prominently stated in the lay press that the capture and clinical use of radon (radium emanation) by the Middlesex Hospital is a "new discovery." In justice to the Radium Institute, will you allow me to say that the technique of treatment by radon tubes has been practised here since 1912, and that the method adopted was published in the annual report of this Institute for that year. Since that date radon tubes have been supplied in steadily increasing number to medical practitioners and hospitals throughout the country, and in the year ending Dec. 31st, 1924, 1067 such tubes were distributed.

I am, Sir, yours faithfully,
A. E. HAYWARD PINCH, F.R.C.S.,
Medical Superintendent, The Radium Institute.

16, Riding House-street, Portland-place, London, W.,
March 30th, 1925.

Obituary.

JOSEPH McGREGOR ROBERTSON, M.A., M.B., C.M. GLASG., F.R.F.P.S. GLASG.

THE medical profession of Glasgow mourns the loss of one of its ablest members through the death of Dr. McGregor Robertson, of 26, Buckingham-terrace, which occurred suddenly on March 17th, after he had addressed a meeting. He had been suffering recently from severe recurrent attacks of influenza, which had weakened his physique, but he refused to take the much-needed rest and carried on his work without pause until the end.

Dr. McGregor Robertson was born in 1858 and educated at Glasgow University, where he graduated M.A. in 1876, and M.B., C.M., with honours, in 1880. He was admitted to the Fellowship of the Royal Faculty of Physicians and Surgeons, Glasgow, in 1892. After graduating, he studied physiology under Du Bois Reymond, Kronecker, and Christiani in Berlin. As a student he was one of the most distinguished men of his year, and was admittedly the best speaker in debate. Then, as always, his clearly defined ideas were emphasised with point and vigour. The well-known professors in Germany with whom he was associated thought him both an able and original investigator, and united in paying tribute to his capabilities and unceasing industry. On his return to Glasgow he was appointed Muirhead Demonstrator of Physiology in the University and, as was customary in those days, he entered private practice as a physician. A distinguished academic life seemed assured, but his success as a physician was so rapid that the claims of his private practice prevented him from following the career for which by temperament, talents, and training he was so pre-eminently fitted. He was specially interested in eye diseases and became one of the surgeons at the Ophthalmic Institute. Recognising the value of radiology, he was amongst the first to instal an X ray apparatus in his private laboratory, and there, despite the increasing calls on his scanty leisure, he pursued throughout his life extensive research work. As an acute clinical observer, and as an accurate diagnostician, he could command the confidence of his patients. Though in chronic ill-health, he pursued ideals of medical practice which will remain an inspiration to all who had the privilege of knowing his work. During the war he was appointed hon. consulting physician of the Royal Naval Hospital, Bute, and to the Princess Louise Scottish Hospital, and latterly accepted a position as physician in the Stobhill Hospital. In 1921 the Royal Faculty of Physicians and Surgeons of Glasgow selected him to represent them on the board of managers of the Western Infirmary.

Dr. McGregor Robertson was an able lecturer with literary gifts which were well shown by his numerous contributions to medical literature. He published in 1884 a treatise on "Physiological Physics," and in 1887 an "Elementary Text-book of Human Physiology," and various papers dealing with such subjects as the Clinical Examination of the Blood, the Employment of Bad Nauheim Waters in Disease, Congenital Pyloric Stenosis and the Quality of Freshness in Food and amount of Light, as related to health and growth. His interests, apart from medical practice, were wide and varied, and he took a leading part in Glasgow in all questions of medical politics and public health.

He is survived by his wife, four daughters, and one son, to whom sympathy will be widely extended.

LABORATORY FOR CHILD STUDY.—The McGill University, Toronto, has given £10,000 from the Laura Spellman Rockefeller Memorial Fund to provide a child study laboratory in connexion with the Faculty of Medicine.

ENDOCRINE THERAPY.

A meeting of the Royal Society of Medicine was held on March 31st, Sir William Hale-White being in the chair, when Dr. W. Langdon Brown opened a special discussion on Endocrine Therapy.

The Clinician's Point of View.

He said that there were five methods of administration of endocrine substances. The oral method was very uncertain except in a few cases of pituitary administration, in which it was difficult to exclude the element of suggestion. The nasal method was originally investigated as a result of the suggestion that this might be a more advantageous route for pituitary preparations since the pituitary itself was an outgrowth of the nasal mucosa. A fair degree of success had been obtained in the treatment of diabetes insipidus in this way, and there was a possibility that adrenalin also might be absorbed by this route. Rectal injection had had a measure of success in selected instances, but subcutaneous injection remained the most effective method of introducing all the substances concerned. Grafting and transplantation were still on trial; the ingrafted material was treated as a foreign body and absorbed so that the action could be but temporary. The results seemed to be better if the graft were placed in some homologous tissue, as, for instance, the insertion of adrenal grafts into the testis, which method had been known to produce a continued life in the graft for over two years. It would be of great advantage if some biochemical tests could be devised to form a standard for investigation of the action of these substances; at present there was only the basal metabolic rate and the blood-sugar. These were probably of wider application than was as yet realised, as were also the more limited tests of the tolerance to quinine hydrobromide and the calcium content of the blood. The difference of opinion between the clinician and the laboratory worker was partly due to the credulity and over-readiness of the former to acclaim untried therapeutic agents, and partly to the fact that the laboratory worker was able to reduce his problem to the simplest possible terms, so that he was liable to forget the much more complicated and delicate adjustments with which the clinician had to deal. Scepticism had even gone so far as to deny the interactions between the endocrine and autonomic nervous systems, but there seemed little doubt that the coöperation between the adrenal, thyroid, and pituitary glands on the one hand and the pancreas and parathyroid on the other, and their mutual antagonism, was supported by a considerable body of experimental evidence. It must be admitted, however, that if polyglandular therapy had a rational basis it was often very irrationally applied. It was scientific nihilism to doubt that the pharmacological reaction to adrenalin and pituitary extract were not due to the glands from which the secretions were extracted. It was easier to believe that there was some coöperation between the adrenal medulla, derived from sympathetic ganglion cells, and the sympathetic nervous system than to refuse to believe that the adrenal medulla played any part in the syndrome resulting from the administration of adrenalin or the stimulation of the post-ganglionic fibres. The thyroid was the gland most widely and most easily administered; the original doses were now known to be too large; never more than 6 gr. per diem of fresh gland extract should be given and the best commencing dose was half a grain three times a day. It was of value for children who showed a failure of growth, nocturnal enuresis, night terrors, ligamentous relaxation, &c. Parathyroid had a great function as a katabolic agent; if its normal secretion were diminished there was an accumulation of waste tissue in the body. It could be absorbed when given therapeutically, producing a great rise in the calcium content of the blood. Adrenal substance seemed to be of little use in substitution therapy; its value lay in its pharmacological action as a local anæsthetic and hæmostatic, in the reduction of spasm and in asthma. It seemed that pituitary might be absorbed by the stomach, but its value as a substitute was doubtful; it might relieve the symptoms of Fröhlich's syndrome and of adiposity, and it was valuable in diabetic conditions and as a stimulant to plain muscle and heart muscle. The use of insulin in diabetes was proved, and the impression that its administration must be for life should be strongly contradicted; many patients were able to return to normal life without the continuance of the drug. Ovarian extract had also proved its value, but the present preparations were not wholly satisfactory. It must be free from corpus luteum and might be of value in thymic asthma and transient glycosuria. Orchitic substance was more doubtful; it was as yet too soon to judge of the value of the grafting methods recently introduced.

The Physiological Aspect.

Prof. Swale Vincent said that there was a great deal to be said on the side of sanity; the present vogue of endocrine therapy was only to be compared with the indiscriminate sale of patent medicines. There should be no essential difference between the laboratory worker and the clinician. If the latter were faced with a more complicated problem to solve, that was all the more reason why he should summon all his scientific accuracy to his aid. It would be hard to find any laboratory worker who would do such bad experiments or be so shameless in publishing them as some of the endocrinologists. Every possible tissue had been hailed as a therapeutic agent and every possible mixture put on the market. In none of them, with one exception, was there more than a little, if any, evidence of any effect whatever being produced when they were taken by the mouth, unless given in sufficient quantity to serve as foods. It was justifiable to regard with great suspicion the report that any pharmacologically inactive substance was of clinical value. Thyroid extract was a very valuable drug leading to prompt and well-recognised effects when given to animals. Thyroxin was less powerful than the extract. Its value in cases of thyroid deficiency was well known and a drug which stimulated the activity of the whole body must be of value in many other conditions. It was by no means clear that any form of tetany was connected with the parathyroids except that variety which followed operations on the thyroid. The parathyroid preparations on the market were pharmacologically inactive, and it was doubtful whether they produced any effect at all when given by the mouth. In animals the tetany due to parathyroid deficiency often disappeared without any substitution therapy; it was probably due to many factors and curable by many forms of treatment. The actions ascribed to the pituitary were very likely due to the hypothalamus. The uses of pituitary extract were not those of substitution therapy. It would be rash to say that the action of adrenalin bore any relation to the adrenal body. There was no effect when given by the mouth with the possible exception of a local action on the lining membrane of the stomach. Ovarian and testicular extracts had no noticeable effects in health or disease beyond a slight irritation. The pancreas was undoubtedly responsible for an internal secretion, the failure of which led to diabetes in animals and probably in man also. Insulin might be obtained from many organs and tissues, though it seemed to originate chiefly in the islets of Langerhans. It ranked with thyroid extract as a very valuable substitution agent, best administered subcutaneously. There was yet much to be investigated; insulin had been obtained from the bodies of animals which had been de-pancreatised some weeks before and from a patient dying of diabetic coma.

Veterinary Endocrinology.

Mr. Leslie Pugh said that the use of endocrine substances in veterinary work did not differ materially from that in medical work. Pituitary was used in obstetrics and thyroid in a variety of conditions. It was found that the amount of milk produced was not altered by the administration of pituitary, but the udder was emptied more quickly, and this action was very useful in cases of cows which would yield milk to a calf but refused to do so for the milker. Milking demanded some degree of coöperation on the part of the cow, and where this was lacking, owing, presumably, to a psychic factor, a dose of pituitrin shortly before milking cured the condition. Corpus luteum extract had been used for sterility in cattle. In cases of slight puerperal infection it often happened that the animal apparently recovered, but the normal ovarian cycle was not resumed. This was found to be due to an unruptured Graafian follicle. If this was removed by rectal manipulation the œstral cycle recommenced within a few days. If it was left the chronic cystic condition combined with the suppression of the normal cycle led to an endocrine disturbance which ended in nymphomania. The combination of thyroid extract with the local manipulation had been found beneficial, especially in curing the ligamentous relaxation which accompanied the puerperal condition. In cases of mummified fœtus pituitary extract was given to expel the fœtus, but was of no use until the corpus luteum of pregnancy had been dislodged. In these cases the corpus luteum did not undergo the changes seen in the later half of a normal pregnancy ; it appeared to go on functioning indefinitely, suggesting that some secretion from the fœtus or placenta might be the cause of its involution. Insulin had been used for the hyperglycæmia and ketosis of cattle.

Cases of Obesity and Defective Growth.

Dr. H. Gardiner-Hill referred to work carried out at St. Thomas's Hospital on some 150 cases of obesity and defective growth. A number of lantern-slides were shown illustrating the changes produced in the body-weight, rate of growth, and carbohydrate metabolism as a result of the administration of thyroid and pituitary extracts together, by the mouth. The whole-gland pituitary preparations alone did not reduce the weight, but seemed to increase the tolerance to thyroid. In both adolescent and adult cases the improvement had been marked and there seemed no doubt that the cases were benefited by the treatment. Posterior pituitary alone had no effect on growth.

Testicular Grafting.

Mr. Kenneth Walker confined his remarks to the effects of testicular extract and grafts. It might be said quite definitely that the oral administration of testicular extract was absolutely useless ; all experiments had been negative. Experiments with grafting were rendered difficult by the scarcity of material and the necessity for careful technique to ensure vascularisation. Voronoff claimed valuable results from his work on the testes of apes, but it seemed that the improvement was rather in the nature of an increase of muscular and mental vigour and general well-being and growth of hair than any specific action on neurasthenia or sexual disabilities. Mr. Walker himself had performed transplantations with human material, using much the same technique as Voronoff and implanting the graft in a serous cavity where it was nourished by the rich exudate until vascularisation could take place. In his experience the grafts survived for two or three months, but there was degeneration of the tubules into cords and the cells regressed to an embryonic condition. Death of the graft did not necessarily mean loss of all the benefit. It might be that the secretion supplied by it tided the patient over a critical period while the compensatory function of other glands was being established. It must not be forgotten that the testis was seldom the whole seat of the trouble ; there was a reciprocal involvement of other glands and structures which could not be affected by a graft. The operation of ligature of the vas deferens led to marked sexual excitement and increase in the interstitial cells of the testis. Steinach's results were impressive, as the life-period was undoubtedly increased in rats, although relapse inevitably occurred sooner or later. In man the results were much less certain ; in some cases there seemed to be no benefit, in others an improvement in the general health. It was by no means certain that the internal secretion of the testis came from the interstitial cells, but this did not nullify the experiment. Mr. Walker had himself done 15 such operations, and although it was difficult to eliminate the element of suggestion it seemed that there had been improvement in 30–40 per cent. He advised the operation in paralysis agitans, as two out of five cases he had done showed marked benefit therefrom.

The debate was adjourned.

Medical News.

University of Oxford : *Radcliffe Prize.*—On the Report of the Examiners the Radcliffe Prize has been awarded by the Master and Fellows of University College to Dr. John M. H. Campbell (Magdalen and New College). The work of Dr. Kenneth J. Franklin, Fellow of Oriel College, was highly commended. The prize is of the value of £50, and is awarded every two years for research work in medicine carried out by a medical graduate of the University.

Radcliffe Travelling Fellowship.—The Master and Fellows of University College announce that, on the Report of the Examiners, the Electors have awarded the Radcliffe Travelling Fellowship, 1925, to Dr. Kenneth J. Franklin, Fellow of Oriel College. The Fellowship is of the annual value of £300, and is tenable for two years, subject to certain conditions of travel and study abroad.

University of Liverpool.—At examinations held recently the following candidates were successful :—

Final Examination for Degrees of M.B. and Ch.B.

Part I.—H. W. Altschul, G. S. Clouston, R. F. Corlett, D. E. Davies, R. W. Eldridge, J. H. Gilchrist, J. Halton, E. Hulme, T. A. Jermy, C. Kaufman, J. C. McFarland, E. P. Moloney, J. Morgan, H. E. Pearson, D. E. Pritchard, Thirza Redman, Mary H. Simpson, and A. K. Wilson.

Part II.—M. A. E. Azzam, H. E. Barrow, W. Howard, J. Katz, G. W. Molyneux, Mary A. Silcock, J. Tarshish, and W. L. Webb.

Diploma in Medical Radiology and Electrology.

I. Davies, A. Gillies, A. J. Murray, and J. R. Parry.

University of Durham : Faculty of Medicine.—At the Convocation held on March 28th the following degrees and licences were conferred :—

Bachelor of Medicine and Bachelor of Surgery.

Joseph F. Hedley, Gwendolen Jones, Maurice H. Jones, William F. Lascelles, Harold Levy, Fenwick Lishman, Charlotte B. Schofield, and Alfred B. W. Smart.

Licence in Dental Surgery.

William J. Collins, John E. Daniels, Robert Moody, Hylton Park, and Ethel Robinson.

At examinations held recently the following candidates were successful :—

Third Examination for Degrees of Bachelor of Medicine and Bachelor of Surgery.

Materia Medica, Pharmacology and Pharmacy ; Public Health ; Medical Jurisprudence ; Pathology and Elementary Bacteriology.—Reuben Abrahams, Harry Birk, Evelyn H. Bolt, Ethel Browell, Basil A. Dormer, and Melville M. Macintyre.

Second Examination for Degrees of Bachelor of Medicine and Bachelor of Surgery.

Anatomy and Physiology.—Second-class Honours : Alfred R. D. Pattison, Coley Goldstein, and James M. Tait. Pass : Hugh M. Brown, David S. Buchanan, William F. Cross, William C. E. Diamond, Ernest A. H. Hindhaugh, James C. V. Hindhaugh, James H. Hudson, Thomas L. Kelly, Harold G. Ungley, and Nora Walkinshaw.

Examinations for the Licence in Dental Surgery.

First Examination (New Regulations).—*Organic Chemistry ; Biology ; Dental Mechanics (Theoretical), and Dental Metallurgy (Theoretical and Practical).*—Thomas H. Brown.

Second Examination (Old Regulations).—*Dental Mechanics ; Dental Metallurgy.*—Jack Abrahams, John Auton, Reginald H. Chapman, and Arthur J. Jackson.

Third Examination (Old Regulations).—*Anatomy, Physiology, and Histology ; Dental Anatomy, Dental Histology, and Dental Materia Medica.*—Philip W. Eddy.

University of Dublin, School of Physic, Trinity College.—At examinations held recently the following candidates were successful :—

Final Medical Examination.

Part I., Materia Medica and Therapeutics ; Medical Jurisprudence and Hygiene ; Pathology and Bacteriology.—*Robert A. Q. O'Meara, *James W. Bowden, *Jack M. Selkon, *Robert E. Hadden, *Thomas J. W. Keown, *John H. M'Lean, John J. O'Dwyer, George W. H. Townsend, Arthur B. Brooks, Johan N. S. Gouws, Myer Hoffman, Cicero G. Nel, Kathleen I. Purdy, Derek St. C. Mackenzie, Gerald O. Taylor, Edward A. Ellis, Gladys L. Craig, Daniel J. Roux, John Johnston, Christina M'Donald, Rachel E. Porter, and John Quigley.

Part II., Medicine.—*Thomas W. MacDowell, Charles F. D. M'Caldin, William C. Somerville-Large, Kathleen D. Murison, George F. Gillespie, Edward M'Alpine, Wilfred H. Anderson, O'Donel T. D. Browne, Joseph R. Gregory, Richard T. Cronin, James Dick, Thomas C. Foster, Paul N. H. Labuschagne, William B. Roantree, Frederick M. Purcell, Norman M. Greeves, François J. Marais, Annie T. Deane, Francis H. M'Kenna, John V. Morris, Robert W. Harte, John Cussen, Gordon P. Bamford, Oliver Chance, William P. E. M'Intyre, Augusta M. Young, William Gallaugher, John L. Levingston, James L. Marshall, Mary Galvin, Francis V. Duke, Christopher Lord-Flood, John A. MacDonnell, Robert A. Heatley, Jerreth Horwich, Harry Nelson, and Ahmed A. Shafik.

Surgery.—*Edward M'Alpine, Roy K. Carson, William A. Redmond, Richard T. Cronin, John A. MacDonnell, Lewis C. Brough, Eric T. S. Rudd, Edward S. A. Crawford, Thomas G. B. Crawford, Frederick M. Purcell, Herbert W. Strong, John M. Johnston, Charles J. du Plessis, Edmund J. Walsh, John E. Beatty, John Crawford, François J. Marais, Leslie M. Whitsitt, Edward A. Bennet, Raymond J. G. Hyde, John G. Maguire, Godfrey W. Garde, William C. G. Potts, Cecil R. Moore, Herbert Birney, Robert V. Franklin, Robert A. Heatley, and Israel Strasburg.

Midwifery.—*Charles R. Bowland, *John F. Wilde, *Robert L. Forsyth, *Elias Rakoff, Elspeth V. D. Hewat, Francis H. M'Kenna, John E. Stokes, Geoffrey D. Edwards, Ahmed A. Shafik, Maurice Sherowitz, Philip B. Robinson, Barend P. Pienaar, Margaret W. Pike, Launcelot W. R. Haskins, Charles E. M'Causland, Wilfred Sinclair, Mary Galvin, Henrietta Armstrong, John E. Beatty, and Wolsey C. Sloan.

Master in Surgery.—Daniel de Bruijn.

Master in Obstetric Science.—David J. Malan.

* Passed on high marks.

INTERMEDIATE DENTAL EXAMINATION.

Anatomy and Physiology.—Andrew A. Gardner, Robert W. Mather, John H. O'Hare, and George M. Titterington.

DIPLOMA IN GYNÆCOLOGY AND OBSTETRICS.

Elizabeth N. Thompson.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Sir Arbuthnot Lane, the President of the Fellowship of Medicine, will preside at the continued discussion on Post-Graduate Study in London, to be held at the house of the Royal Society of Medicine, 1, Wimpole-street, London, W., on Wednesday, April 8th, at 6 P.M. It is hoped that members of the medical profession who are able to attend will do so and will voice their views for the improvement and extension of post-graduate work.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The twenty-third meeting of this Commission was held at the Home Office, Whitehall, on March 26th, Sir Andrew Duncan in the chair. Evidence was given on behalf of the Federation Committee of English, Scottish, and Welsh Insurance Committees by the Rev. W. D. Yoward, vice-chairman, Mr. Edwin Potts, hon. secretary, Mr. W. M. Marshall, ex-chairman, and Mr. F. Llewellyn Jones, chairman of the Federation, the administrative work of the Insurance Committees and questions of the extension and improvement of medical and treatment benefits being fully dealt with. Thereafter Mr. Marshall gave evidence on the features peculiar to Scotland and Mr. Llewellyn Jones on the Welsh position. Mr. Eynon Lewis then gave evidence on behalf of the Glamorgan County Insurance Committee with special reference to the South Wales Medical Institutes. The Commission announce that proof copies of the oral evidence and the relative statements submitted at the meeting of March 12th are now on sale at H.M. Stationery Office (3*s*.).

NATIONAL ASSOCIATION FOR THE PREVENTION OF TUBERCULOSIS.—The Eleventh Annual Conference of the Association will be held in London on Monday and Tuesday, July 6th and 7th. The main object under consideration will be Tuberculosis in Childhood, and the address introductory to the discussion will be given by Prof. Pirquet, of the University of Vienna. The afternoon of the second day (July 7th) will be devoted to addresses on the Treatment of Tuberculosis by Sanocrysin, by Prof. Holger Möllgaard, Professor of Physiology, Royal Veterinary and Agricultural College, Copenhagen, and Prof. Knud Faber, of the University of Copenhagen. The meetings will be held at the Robert Barnes Hall (Royal Society of Medicine), 1, Wimpole-street, W. 1. The conference is open to all persons interested in tuberculosis on payment of a fee of one guinea, which includes a copy of the report of the proceedings. The Council of the Association announces that the Minister of Health will be prepared to sanction under the Local Authorities (Expenses) Act the payment of the reasonable expenses of not more than three delegates, among whom should be included the medical officer of health or chief clinical tuberculosis officer, or both, from county councils, county borough councils, joint tuberculosis committees, and metropolitan borough councils. Further particulars may be obtained from the Secretary at 20, Hanover-square, London, W. 1.

THE LATE MR. JAMES TAYLOR.—The death occurred at his residence in Clifton, Bristol, on March 22nd, of Mr. James Taylor, M.R.C.S., L.S.A., who was the son of a well-known Bristol surgeon. Mr. Taylor qualified some 50 years ago and was one of the first medical men in Bristol to become interested in Rontgen rays. During the war he was a captain in the R.A.M.C. (Territorials), and was radiologist to the Bristol Royal Infirmary, where at the time of his death he was consulting radiologist. Mr. Taylor made many friends and was beloved by all his patients, though ill-health of recent years prevented his attendance on any but those whom he had known for many years. Keenly interested in everything that concerned Bristol, he took a prominent part in many local movements; he was a good sportsman and an enthusiastic Freemason.

LISTERIAN SOCIETY.—The Listerian Society of King's College Hospital met under the presidency of Mr. C. P. G. Wakeley on March 24th, for the purpose of conducting a trial in accordance with the rules of legal procedure. The charge was one of manslaughter, and the counsel for the defence was Mr. J. Forster, of the Inner Temple, and the prosecution was conducted by Miss Llewelyn Davies, of the Inner Temple. The conduct of the medical aspects of the charge was under the direction of the Sambrooke Registrars, Dr. Livingston and Mr. A. C. Edwards. Mr. Justice McCardie was the judge, and greatly contributed to the proceedings by a learned summing-up dealing with the law on the subject. As a means of learning court procedure and securing confidence in giving evidence the proceedings of the evening were admirably adapted to be useful and instructive to the students, who warmly expressed their appreciation of the presence of the judge after an exacting day in the Royal Courts of Justice.

THE LATE DR. A. W. BEAUMONT.—Albert William Beaumont, who died on March 26th in his seventy-first year, was a well-known practitioner in East Ham. He graduated in Arts at the University of Cambridge in 1877, and then turned to the study of medicine at St. Mary's Hospital Medical School, and later in Dublin. He qualified L.S.A. in 1882, L.R.C.S. & L.M. Edin. in 1885, and M.D. Dub. in 1898. He practised for a time in Cambridge, in 1886 moved to Beckton, and later to East Ham, where for 22 years he was medical officer of health, and for nearly 30 years surgeon to the West Ham Guardians. He was also consulting surgeon to the East Ham Cottage Hospital. He was surgeon to the Gas Light and Coke Company for 39 years. Dr. Beaumont leaves a widow and two sons, both of whom follow their father's profession, and two daughters.

CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.—The fifth British Congress of Obstetrics and Gynæcology will be held in London at the rooms of the Royal Society of Medicine, from April 22nd to 24th inclusive, under the presidency of Dr. Russell Andrews. The constituent societies of the congress are the Section of Obstetrics and Gynæcology of the Royal Society of Medicine, the Edinburgh Obstetrical Society, the North of England Obstetrical and Gynæcological Society, the Midland Obstetrical and Gynæcological Society, the Section of Obstetrics and Gynæcology of the Royal Academy of Medicine, Dublin, and the Ulster Medical Society. Prof. W. Blair Bell, Dr. R. W. Johnstone, Sir Ewen J. Maclean, Dr. T. W. Eden, and Mr. T. G. Stevens form the Executive Committee, the last two being respectively the chairman and treasurer. Prof. J. Whitridge Williams, of Baltimore, and Prof. W. W. Chipman, of Montreal, will be the official guests. In addition to the president, the chairmen of the various sessions will be Dr. J. E. Gemmell, Prof. B. P. Watson, Prof. T. Wilson, and Dr. L. L. Cassidy, and communications will be made by Dr. Gibbon FitzGibbon, Prof. J. Munro Kerr, Dr. J. W. Bigger, Dr. L. P. Lockhart, Prof. J. H. Teacher, Dr. Bethel Solomons, Prof. A. Donald with Dr. K. V. Bailey, Dr. Wilfred Shaw, Dr. G. I. Strachan, Dr. Malcolm Donaldson, Dr. Agnes Bennett, Prof. Louise McIlroy, and Dr. E. P. Williams. On Wednesday, April 22nd, there will be a luncheon at Pagani's Restaurant given by the Section of Obstetrics and Gynæcology of the Royal Society of Medicine, and on the same evening at 9 o'clock the President and Mrs. Russell Andrews will entertain members of the congress and their friends in the rooms of the Royal Society of Medicine. The congress dinner will be held at the Criterion Restaurant on the evening of Thursday, April 23rd. Arrangements have been made with the principal hospitals for members of the congress to be present at operations, and a pathological exhibition will be held. The hon. secretaries are Mr. Clifford White, 62, Harley-street, W. 1, and Mr. J. Barris, 50, Welbeck-street, W. 1, and advance copies of the reports from the various bodies on the Prognosis and Treatment of Puerperal Sepsis can be obtained from Mr. Clifford White if application is made before April 10th.

Rebuilding of Middlesex Hospital.—The rebuilding of this great hospital on its present site will cost about half a million, and it is intended next month to launch "the largest appeal ever made in this country for any single hospital." The new building will include a paying patients' wing and greatly enlarged and improved accommodation for the nursing staff, which numbers nearly 200.

Rontgen Society.—A general meeting of this society will be held on Tuesday, April 7th, at 8.15 P.M., in the British Institute of Radiology, 32, Welbeck-street, London, W. Mr. R. Craig Rodgers will read a paper on the Organisation and Equipment of X Ray Rooms arranged for Private Radiologists, and Mr. G. T. Loughborough will read a paper on Acute X Ray Burns The eighth Silvanus Thompson Memorial Lecture will be delivered by M. Le Duc de Broglie, Paris, during the International Congress of Radiology, to be held next July, and the Mackenzie Davidson Memorial Lecture will be delivered by Sir Berkeley Moynihan, also at a meeting to be held during the International Congress.

The Local Government Act, Ireland.—The Local Government Act became law last week, having been under discussion in the Oireachthas for nearly a year. It makes notable changes in the machinery of local government in the Free State. The county is now to be the only unit for administration and sanitary purposes. The rural district councils are abolished. From the medical point of view the most important provision of the Act is that for the appointment of a medical officer of health for each county area. Certain changes are also made in the laws regarding pensions of officers of local authorities, but medical officers are not injuriously affected. Among the statutes repealed by the present Act is the Ministry of Health Act (Ireland), 1919, and with it goes the Irish Public Health Council.

Donations and Bequests.—Mrs. Elizabeth Shaw, of Kensington, W., and Newbury, Hants, left by will £1000 to St. Bartholomew's Hospital and £1000 to the Hospital for Incurables, Putney.—Mr. Robert Meggitt, Uplands, Richmond, Surrey, bequeathed £5000 to Richmond Royal Hospital. The testator also directed that £15,000 be divided among the Royal Hospital for Incurables, Putney Heath, King Edward's Hospital Fund, London, the London Hospital, London Orphan School, Watford, and Dr. Barnardo's Homes. He also left £500 for distribution among the poor of Richmond.—At the annual meeting of University College, London, it was announced that Mr. Geoffrey Duveen, in addition to his generous gift of £15,000 of last year, had given £50,000 for the construction and equipment of a new Royal Ear Hospital, which will contain 42 beds for in-patients and ample room for the treatment of out-patients, and will embody all the latest improvements in hospital construction and equipment.—Under the will of Mrs. Jane Lewis, of Hackney, in accordance with the views of the testatrix, £22,000 will be devoted to the erection of a new wing to the Royal Victoria Eye and Ear Hospital, Dublin.—The widow of Mr. Tetley, a director of Courtauld's, Ltd., in fulfilment of her husband's desires, is distributing £40,000 amongst the charities in Leigh, Flint, and Coventry, and other places where Courtauld's had works. The treasurer of Leigh Infirmary has received £4000 from the fund for the infirmary, and £1000 for Leigh Sick Nursing Association.—Representatives of the trustees of the Treloar Cripples' Home, Alton, on Feb. 20th received at Portsmouth a cheque for £10,000, being the amount raised in the town for the establishment of a ward for the treatment of Portsmouth's 500 crippled children.—Lord Bledisloe is giving one half of his salary as Parliamentary Secretary to the Ministry of Agriculture to the Lydney and District Cottage Hospital.—Bradford Woolcombers, Ltd., are contributing £13,000 towards the building fund of the contemplated new Bradford Royal Infirmary.—Sir Louis Pearson, who has just retired from the presidency, has promised £5000 towards the extension fund of the Nottingham General Hospital.—Princess Louise has made a donation of £1000 to the Princess Louise Hospital for Children, Kensington.—Lord Leverhulme has sent a donation of £1000 in connexion with the appeal to rebuild the Kensington, Fulham, and Chelsea General Hospital.—Mr. Daniel Henry Shilson, of St. Austell, Cornwall, left, among other bequests, £1000 each to the Royal Cornwall Infirmary and the St. Austell Nursing Association.—The Government of Sierra Leone has sent £500 towards the funds which are being raised for the foundation of the Ross Institute and Hospital for Tropical Diseases.—The Chelsea Hospital for Women has received a donation of £100 from the Westminster Bank, Ltd., acting in the distribution of the charitable bequests of the late Mr. George Macbain.—The Royal Medical Benevolent Fund Guild gratefully acknowledges a donation of £200 from Mr. George Macbain, deceased, per Westminster Bank, Ltd.

THE BATEMAN APPEAL.

As already explained in The Lancet, it has been felt that material assistance ought to be offered to Dr. Bateman to meet the legal expenses of his recent successful appeal against conviction and to make good the deficiency in his professional income. Accordingly, the Bateman Fund has been opened and lists of contributions have appeared in recent issues. We have received additional contributions as follows:—

	£	s.	d.
Already received and acknowledged ..	401	19	0
Prof. A. L. McIlroy	5	5	0
Prof. W. Blair Bell	3	3	0
Dr. L. Franklin	3	3	0
Anonymous	2	2	0
Dr. F. A. M. Flegg	1	1	0
Dr. F. S. D. Hogg	1	1	0
Dr. G. Hollings	1	1	0
Dr. J. Macdonald	1	1	0
Dr. W. W. Maxwell	1	1	0
Dr. H. P. Miller	1	1	0
Dr. H. T. Nixon	1	1	0
Dr. C. E. Silvester	1	1	0
Dr. J. H. Waddington	1	1	0
Dr. R. S. Corey	0	10	6
A. M. W.	0	10	0
Dr. H. S. Hollis	0	2	6

Remittances should be forwarded to the Manager of The Lancet, 423, Strand, W.C. 2, and made payable to the "Bateman Fund Account."

Parliamentary Intelligence.

HOUSE OF LORDS.

Tuesday, March 31st.

Dogs Protection Bill.

Lord Banbury, in moving the second reading of the Dogs Protection Bill, said that a similar measure had three times passed the second reading stage in the House of Commons, and on one occasion was reported to the House from a Standing Committee without amendment. The passing of the Bill would in no way prevent experiments from being made on other animals; all it would do was to prevent them from being made on dogs. He was aware that very many medical men were against the Bill, but on the other hand many were in favour of it. The use of dogs in vivisection was unnecessary.

Viscount Knutsford, in moving the rejection of the Bill, said he did not suppose the whole medical and surgical world had ever been so unanimous on any subject as it was on this question. They were all reluctant to use dogs for experiments, but they were compelled to do it because it was necessary for the advance of knowledge. Sir Frederick Treves, who was always quoted at anti-vivisection meetings, wrote: "No one could be more keenly aware than I am of the great benefits conferred on suffering humanity by certain researches carried out by means of vivisection." Diabetes was no longer a sentence of death on young boys and girls, and was no longer an intolerable burden on adults, thanks wholly and solely to experiments on dogs.

Lord Lambourne supported the Bill.

Lord Mildmay of Flete, who opposed the Bill, said only last Friday he presided over the Medical Research Council in the absence of Lord Balfour, and he had been authorised to make known how strong and unalterable was the objection of its members to this Bill as likely seriously to impede the progress of medical science and greatly to retard the successful treatment of disease. His experience on the Medical Research Council, and in connexion with the management of the Middlesex Hospital, had convinced him that in no walk of life were to be found more admirable qualities and beautiful characters than those engaged in medical research.

Lord Rayleigh said some persons thought that a respectable minority of the medical profession were in favour of the Bill. He had had an opportunity of going through the names which the noble lord had brought forward a year ago as being on his side, and so far as he had been able to learn not one of those men had ever made a discovery of any kind.

Lord Buckmaster said their lordships ought to hesitate a very long time before they attempted to limit the area of investigation into the means by which it might be possible to extend the wide boundaries of the great empire of learning, to check the progress of disease, and even to stay the swift and stealthy foot of death.

Lord Desborough said the Home Office were as opposed to the Bill now as they were last year.

The Bill was rejected by 77 votes to 8.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 25TH.

Women Doctors in the Civil Service.

Miss WILKINSON asked the Chancellor of the Exchequer whether there were any classes of men and women civil servants in receipt of equal pay; and, if so, why the principle was applied in some cases and not in others.—Lieut.-Col. W. GUINNESS (Financial Secretary to the Treasury) replied: There are a few medical posts in the Civil Service in which men and women doctors receive the same rate of pay. In these cases special circumstances exist and no general principle has been applied.

Food Preservatives.

Mr. MACKENZIE LIVINGSTONE asked the Minister of Health if he was aware that in the draft Rules of March 17th. 1925, on preservatives in foods there was a list of prohibited coal-tar products which gave the impression that all other such products might be used; and would he take steps to lay down the quantities of lead and arsenic permitted in such compounds, and thus carry out the recommendations of the committee.—Sir KINGSLEY WOOD replied: Yes, sir. The effect of the regulations, as drafted, is that all coal-tar colours which are not included in the schedule may be used in food until they are shown to be injurious to health. Although lead and arsenic are occasionally present in coal-tar products, my right hon. friend is advised that the percentage of those substances liable to be introduced into foodstuffs through this medium is so minute that it is unnecessary to extend the scope of the regulations in the direction suggested.

Mr. GERALD HURST asked the Minister of Health whether he was aware of the alarm occasioned to the confectionery, bakery, and allied trades by the draft regulations as to the use of preservatives and colouring matter in articles of food; whether he was aware of the strong scientific evidence published against prohibition of boric acid and against the new rules as to liquid eggs, butter, margarine, and cream; and if the regulations could be held up until the House could consider their propriety.—Sir KINGSLEY WOOD replied: My right hon. friend has received representations from these trades and I am arranging to meet a deputation. My right hon. friend is satisfied that the scientific evidence regarding the effect of boric acid was thoroughly considered by the Departmental Committee on Preservatives in Food. My right hon. friend is desirous of giving the fullest consideration to the views of all parties concerned, and thinks the hon. Member will agree that that end will be secured by the discussion of the draft with representatives of trade bodies and others before the regulations are made and laid before Parliament.

THURSDAY, MARCH 26TH.

Maternity and Child Welfare Centres.

Mr. BENJAMIN SMITH asked the Minister of Health what progress had been made as regards the establishment of new maternity and child welfare centres since the issue of the circular of Feb. 8th, 1924, by the late Government.—Mr. N. CHAMBERLAIN replied: Since the issue of the circular of Feb. 8th, 1924, the number of maternity and child welfare centres in England known to my department has increased from 1986 to 2112, and proposals for about 30 additional centres are under consideration. Additional sessions for infant consultations, antenatal work, massage, &c., have also been provided at 95 existing centres.

Penalties on London Panel Doctors.

Mr. HERBERT WILLIAMS asked the Minister of Health why penalties of £10 and £20 respectively were imposed on two doctors who had been accused by the London Insurance Committee of gross negligence in cases of appendicitis and diphtheria, respectively, but who had been found innocent by a committee appointed by the Ministry of Health.—Mr. N. CHAMBERLAIN replied: As misapprehension has arisen regarding these cases I will state the facts fully. The death of two insured persons in London in 1924 led to complaints being lodged with the London Insurance Committee in regard to the treatment received by them from the two insurance practitioners concerned. These complaints were investigated by the Medical Service Subcommittee of the Insurance Committee which, with the concurrence of its medical members, recommended that in both cases a substantial deduction should be made from the doctors' remuneration. The Insurance Committee itself, however, regarded the cases as cases of gross negligence and accordingly made representations to me under the regulations for the removal of both doctors from the Medical List. These representations necessitate the appointment of an Inquiry Committee. That Committee, consisting of a barrister and two medical practitioners, found that the allegation of "gross" negligence was not established in either case, but their findings of fact indicated that in one case the doctor had failed to exercise reasonable care, and that in the other case the doctor had failed to respond to a request to visit the patient at what proved to be a critical period in the illness. After careful consideration of the reports of the Committee, I came to the conclusion that while the facts established were not such as to warrant the removal of either practitioner from the Medical List, there was abundant ground for the original recommendation of the Medical Service Subcommittee that grant should be withheld. My hon. friend will see from the above that there is no ground for the statement that the practitioners were found innocent. I may add that the procedure followed in these cases presents no exceptional features but follows the practice of the Insurance Commissioners and of previous Ministers of Health.

Standard of Condensed Milks.

Mr. GROVES asked the Minister of Health the terms of any order issued by his department regulating the standard of quality for imported condensed milk.—Mr. N. CHAMBERLAIN replied: The Public Health (Condensed Milk) Regulations, 1923, require that full-cream condensed milk must contain 31 per cent. of milk solids including 9 per cent. of milk fat, and that skimmed condensed milk must contain 26 or 20 per cent. of milk solids according as it is sweetened or not.

Livestock Depôt at Barnet.

Lieut.-Col. FREMANTLE asked the Minister of Health if his attention has been drawn to the serious nuisance occasioned by the establishment in the old posting-stables at Barnet of a livestock depôt immediately adjoining a street of small houses; whether he was aware that as many as 600 monkeys had been confined on the premises at a time and that several had escaped into neighbouring houses and gardens, to the alarm and great possible danger to the mental health of the inhabitants; and whether he would take action to secure the protection of the people of Barnet from this standing menace.—Mr. N. CHAMBERLAIN replied: I am communicating with the District Council on the subject mentioned by my hon. and gallant friend. I may mention that the model by-laws prepared by my department for preventing the keeping of animals in such a way as to be injurious to health do not apply to monkeys, but there is no reason why local by-laws should not include these animals if necessary.

Treatment of Tuberculosis.

Mr. W. C. ROBINSON asked the Minister of Health what increased provision for the treatment of tuberculosis had been made since the issue of the circular of Feb. 8th, 1924.—Mr. N. CHAMBERLAIN replied: Since the issue of the circular of Feb. 8th, 1924, proposals for the provision of more than 1300 additional beds have been approved. In addition, local authorities have been authorised to take additional beds at institutions belonging to voluntary bodies, and to carry out other developments of their tuberculosis schemes. The number of persons under treatment in residential institutions has increased by nearly 1300 since Feb. 1st, 1924, whilst the total net expenditure by local authorities which is about to be authorised for 1925-26 is £100,000 in excess of the estimated net expenditure during the current year. The figures quoted relate to England only.

National Health Insurance Surplus.

Major WHELER asked the Minister of Health whether, seeing that the unspent accumulated insurance funds amounted to nearly £100,000,000 for England under the National Health Insurance Act why it was necessary to have so large a sum in reserve.—Mr. BENNETT asked a similar question.—Mr. N. CHAMBERLAIN replied: The need for the reserves referred to by the hon. Members arises from the fact that the liabilities under the system of National Health Insurance increase with the age of the insured persons, while the contributions in all cases are at fixed rates payable from age 16 to age 70, and are actuarially calculated to be sufficient for a person entering into insurance at the age of 16. The question where funds accumulate in particular cases in excess of requirements is determined by the quinquennial valuations made under the Act. Where disposable surpluses appear, the societies are authorised to distribute them in additional benefits under schemes confirmed by my department. On the last valuation over £6,000,000 of surplus funds was so dealt with, and it is expected that on the valuation now in progress a considerably greater sum than this will be made available for distribution.

Segregation of Infectious Patients.

Colonel DAY asked the Minister of Health if he would consider appointing a court of inquiry to investigate and report on the prevailing conditions of the public health service of the country, and to inquire especially into the compulsory segregation of persons seriously affected with tuberculosis and in an infectious and incurable condition; and would he take steps to provide adequate protection to the children and near relatives of such persons who, through lack of housing accommodation, were forced to live in close proximity to such persons.—Mr. N. Chamberlain replied: As at present advised I see no necessity for such an inquiry as is suggested. As regards the compulsory segregation of persons suffering from tuberculosis and in an infectious state, I may point out that legislation on this subject has already been obtained by a number of local authorities, and possibly an opportunity of dealing with the matter generally, as has been recommended by the local legislation committee, may occur in connexion with the Public Health Bill which secured a second reading on Friday last. As regards the last part of the question, it is for the local sanitary authorities to take all such steps as are practicable to prevent the spread of infection.

Royal Commission on Mental Disorders.

Captain Waterhouse asked the Minister of Health when the Report of the Royal Commission on Mental Disorders might be expected.—Mr. N. Chamberlain replied: It is not possible at this stage to state when this Report may be expected, but I understand that the Royal Commission hope to be in a position to present their Report early next year.

The Bastardy Bill.

Captain Bowyer asked the Prime Minister whether he would give facilities for the Second Reading of the Bastardy Bill.—Mr. Baldwin replied: The Government do not propose to grant special facilities for this Bill.

Insanitary Houses in West Ham.

Mr. Groves asked the Minister of Health whether he would cause special inquiries and efforts to be made in respect to the condition of houses within the county borough of West Ham, inasmuch as it was the common feature of the town council to receive reports monthly from its chief sanitary and medical advisers indicating that over 75 per cent. of the houses examined were found to be not in all respects reasonably fit for human habitation, and for the year 1923 of 11,207 houses so examined 8380 were in such a state that notices were required to be served upon the owners or rack-renters; and would he consider whether special action was necessary.—Mr. N. Chamberlain replied: I am aware of the conditions in this borough. The local authority are making active use of their powers under the Public Health Acts, and I understand that they are considering whether action should be taken in particular cases under Section 28 of the Housing, Town Planning, &c. Act, 1919, as amended by Section 10 of the Housing, &c. Act, 1923. These existing powers should, I think, prove to be sufficient.

Certification of Death.

Lieut.-Col. Fremantle introduced a Bill to amend the law relating to the certification of deaths, which was read a first time.

Monday, March 30th.

Vaccine and Serum for Pig Erysipelas.

Lieut.-Col. Fremantle asked the Minister of Agriculture if his attention had been called to the value of the specific vaccine and serum, at present only obtainable from the continent, for the prevention of pig erysipelas; and if he would arrange for this remedy to be stocked by veterinary surgeons throughout this country.—Mr. Wood replied: The reply to the first part of the question is in the affirmative. I would point out that for the last 20 years the Ministry has issued a leaflet on swine erysipelas which, among other things, describes vaccine and serum treatment. I understand that at present supplies are only obtainable from the continent, because the demand has not been such as to encourage firms in this country to stock the material. I have no power to arrange for this remedy to be stocked by veterinary surgeons throughout the country, but no doubt veterinary surgeons and firms will do so, if pig owners will show them that there is a sufficient demand.

Import of Arsenic from Japan.

Captain Moreing asked the President of the Board of Trade what quantities of arsenic were imported into the United Kingdom from Japan during the months of December, 1924, and January and February, 1925.—Mr. A. M. Samuel (Parliamentary Secretary to the Overseas Trade Department) replied: The quantity of white arsenic and other arsenic compounds imported into Great Britain and Northern Ireland, and registered as consigned from Japan, amounted to 51 tons in December, 1924, 104 tons in January, 1925, and 81 tons in February, 1925. There were no imports of metallic arsenic during the months in question.

The Lee Commission and Indian Provincial Services.

Mr. Wardlaw-Milne asked the Under Secretary of State for India whether any decision had been come to with regard to the claims of those members of the provincial services who had retained their non-Asiatic domicile to have extended to them the benefits conferred on their colleagues in the covenanted services by the Act of 1919 and by the Report of the Lee Commission, in so far as these latter had been adopted; and whether, in the event of the matter not having been decided, due attention would be paid to the recommendations on the subject contained in the letter from the Viceroy of India to the Secretary of State for India, dated Delhi, March 5th, 1919, and in the Report of Lord Southborough's Committee.—Earl Winterton replied: My noble friend is considering the position of the officers to whom my hon. friend draws attention, and in making his decision will bear in mind the papers referred to.

Permanent Appointments to Pensions Medical Staff.

Colonel Day asked the Minister of Pensions what was the name and rank of those members of the medical staff of the Ministry who had been given permanent appointments; what increase had been made in their salary; and whether other temporary officers of the Ministry who were given established posts would receive a similar relative salary.—Major Tryon replied: It is intended to recommend 48 members of the existing whole-time temporary medical staff for permanent appointments, but no such appointments have yet been made. The successful candidates will enter their new posts at their existing rates of pay, subject, in a few cases, to certain slight adjustments, up or down, which may be made in order to remove existing anomalies. In regard to the last part of the question, the terms and conditions governing the grant of established posts to other classes of temporary employees of the Ministry will necessarily be those laid down for such classes in Government departments.

Boron Preservatives in Food.

Mr. Goodman Roberts asked the Minister of Health (1) whether he was in possession of any evidence that the small quantities of boron preservatives permitted to be used in liquid eggs was deleterious to health; and, if so, would he state its nature; and (2) whether it had been decided to prohibit the use of boron preservatives in liquid eggs; and whether, before issuing regulations on this matter, he would consider the probable increased cost of important foodstuffs into the composition of which eggs enter, seeing that there was no adequate provision for cold storage in this country to make cold-storage eggs a practical substitute for liquid eggs.—Mr. N. Chamberlain replied: The effect of boron preservatives was considered by the departmental committee on the use of preservatives in food, and they were unanimously of opinion that such preservatives are sufficiently harmful to justify their total prohibition. I have not yet settled the final form of the regulations, and before doing so I shall certainly give full weight to such considerations as those mentioned by the hon. Member.

Tuesday, March 31st.

Chemical Warfare Tests on Soldiers.

Mr. Dunnico asked the Secretary of State for War whether, with regard to the fact that at the camp of the chemical warfare research department at Salisbury Plain experiments were being carried out to test the relative effects of poison gas on soldiers, he would say whether any men subjected to these tests had been seriously and permanently injured in their lungs and otherwise, and whether he was prepared to put a stop to such experiments.—Sir L. Worthington-Evans replied: No men have suffered injury to their lungs or otherwise through being subjected to these tests. The answer to the second part of the question is in the negative.

Mr. Ammon asked the Secretary of State for War with regard to the experiments as to the effect of poison gases on young soldiers which were conducted at the chemical warfare research department, the number of such experiments, and the number of young soldiers engaged in them since 1918.—Sir L. Worthington-Evans replied: The number of such experiments since 1918 is 372 and the number of soldiers engaged in them 188. All these soldiers voluntarily offered themselves for this special duty.

Mr. Ammon asked the Secretary of State for War the nature of the experiments conducted at the chemical warfare research department by subjecting young soldiers to the effects of poison gases; what precautions were taken to prevent such experiments resulting in injury to the young soldiers concerned; and the number of young soldiers who had been injured in their lungs and otherwise since 1918.—Sir L. Worthington-Evans replied: The experiments fall under three categories: (1) exposure to low concentrations of gases to ascertain their physiological properties; (2) exposure to gas of personnel protected by respirators in order to test the protective efficiency of the respirators; (3) tests on skin of human personnel of new compounds to ascertain their irritant action, if any. All such experiments have been carried out under most stringent regulations which have been framed on the best medical advice obtainable, in order that the health of the observers concerned may be safeguarded. There have been no cases in which injury to the lungs or otherwise has been caused to soldiers since 1918.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, April 6th.

WAR: at 4.30 P.M.
Annual General Meeting:
Election of Officers and Council for Session 1925–26.
Papers:
Colonel J. Crawford Kennedy, R.A.M.C.: Tuberculosis in the Army.
Surgeon-Commander C. H. Dawe, R.N.: Tuberculosis in the Navy.
Wing-Commander H. A. Treadgold, R.A.F.: Tuberculosis in the Royal Air Force.

Tuesday, April 7th.

ORTHOPÆDICS: at 8.30 P.M.
Discussion:
Differential Diagnosis of Non-Tuberculous Coxitis in Children and Adolescents.
To be opened by
Mr. Alan Todd, followed by Mr. R. C. Elmslie and Mr. H. A. T. Fairbank (President).

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, April 6th.—12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.

TUESDAY.—10 A.M., Medical Registrar: Clinical Methods. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—2 P.M., Dr. Burnford: Medical Wards. 2 P.M., Dr. Owen: Medical Out-patients. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—11 A.M., Sir Henry Simson: Gynæcological Wards. 12 noon, Mr. Sinclair (Lecture): Abdominal Surgery. 2 P.M., Mr. MacDonald: Genito-Urinary Dept.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, April 7th.—4.15 P.M., Mr. W. R. Douglas: Benign Swellings of the Breast.

Appointments.

DODDS, R. L., M.B., B.Ch. Belf., has been appointed Resident Medical Officer to the Freemasons Hospital and Nursing Home, Fulham-road, S.W.

FFRENCH, E. G., M.D., F.R.C.S.E., M.R.C.P. Lond. (Lieut.-Colonel R.A.M.C., retd.), Dermatologist to the London Temperance Hospital.

MACLENNAN, N. M., M.B., Ch.B. Aberd., D.P.H., Assistant Medical Officer of Health, Woolwich.

MCMILLAN, KENNETH, F.R.C.S. Eng., Hon. Surgeon to the Birmingham and Midland Hospital for Women and Hon. Assistant Surgeon to the Birmingham Maternity Hospital.

MOORE, FREDERICK CRAVEN, M.Sc., M.D., F.R.C.P., to the Chair of Systematic Medicine in the University of Manchester.

SINCLAIR, A. H. H., M.D., C.M., F.R.C.S. Edin., a Medical Referee under the Workmen's Compensation Act, in place of Sir George A. Berry, who has resigned.

THACKRAY, C., M.D., B.S. Lond., Medical Superintendent of St. Pancras Guardians' Highgate Infirmary.

Queen Charlotte's Maternity Hospital: STORY, A. G., M.B., B.Ch., Resident Medical Officer; SAUNDERS, ROY M., M.B., Ch.B. Edin., and FOOTE, ROBERT, M.R.C.S., L.R.C.P. Lond., Assistant Resident Medical Officers.

Certifying Surgeons under the Factory and Workshop Acts: CABLE, J. E., M.B., Ch.B. Aberd. (Forfar); EWING, H. W., M.R.C.S., L.R.C.P. Lond. (Buntingford); WARNOCK, J. (Leeds, South).

Vacancies.

For further information refer to the advertisement columns.

Barnsley, Beckett Hospital and Dispensary.—H.P. and Jun. H.S. Each at rate of £140.

Brighton, Royal Alexandra Hospital for Sick Children.—H.S. £100.

British Hospital for Mental Disorders, &c., 72, Camden-road, N.W. Hon. P.

Chester, City and County of.—Asst. M.O.H. and Asst. Sch. M.O. £600.

Croydon County Borough.—Deputy M.O.H. and Dep. Sch. M.O. £780.

Derby County Borough Isolation Hospital and Sanatorium.—Res. M.O. £550.

Derby, County Mental Hospital, Mickleover.—Jun. Asst. M.O. £350.

Derbyshire County Sanatorium, near Chesterfield.—Res. Asst. M.O. £350.

Derbyshire Royal Infirmary.—H.S. £200.

Dewsbury County Borough.—M.O.H. £900.

Durham County and Sunderland and Eye Infirmary, Stockton-road, Sunderland.—H.S. £450.

Fulham Infirmary, St. Dunstan's-road, Hammersmith, W.—Third Asst. M.O. £250.

Hôpital and Dispensaire Français, 172, Shaftesbury-avenue, W.C.—P. to Out-patients.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—H.P. £50.

Hospital for Diseases of the Throat, Golden-square, W.—Hon. Surg. Reg.

Huddersfield, Ministry of Pensions Mental Hospital, Kirkburton.—Sen. M.O. £600.

Lambeth Parish, Brook-street, Kennington-road, S.E.—Public Vaccinator.

Leeds Public Dispensary.—Jun. Res. M.O. £150.

Liverpool Eye and Ear Infirmary.—H.S. £100.

London Lock Hospital, 91, Dean-street, W.—H.S. at rate of £200. Also Temp. Hon. S. to Out-patients.

London Temperance Hospital, Hampstead-road, N.W.—Surg. Reg. 40 guineas.

Manchester Royal Infirmary.—Asst. Res. Surg. O. at rate of £150.

Metropolitan Hospital, Kingsland-road, E.—H.P., H.S., Jun. H.P., Jun. H.S. and two Cas. O.'s. Each at rate of £100. Also Surg. for Dis. of Nose, Throat, and Ear.

Middlesex Hospital Medical School.—University Chair of Biochemistry. £800.

Ministry of Health, Whitehall, S.W.—M.O.'s. £800.

Newcastle-upon-Tyne City Hospital for Infectious Diseases.—Res. Med. Asst. £350.

Newcastle-upon-Tyne, City and County of.—Tub. M.O. £750.

North Marylebone School of Mothercraft.—M.O. for Infants Clinic. 1½ guineas per session.

Oldham Union, Poor Law Institution, Rochdale-road.—Res. Asst. M.O. £300.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Surg. Reg. and Hon. Med. Reg. Each £200. Also Hon. Asst. S. to Ear, Nose, and Throat Dept.

Putney Hospital, Lower Common, Putney, S.W.—Res. M.O. £150.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Obstet. S.

Royal Chest Hospital, City-road, E.C.—Phys.

Royal Northern Hospital, Holloway, N.—H.P. and H.S. Each at rate of £75.

Salford Union Infirmary, Hope, Pendleton, near Manchester.—Radiologist. £150.

Sheffield Royal Infirmary.—H.S. £80.

Sheffield, University Royal Hospital.—Asst. Pathologist and Demonstrator of Pathology.

West End Hospital for Nervous Diseases, Welbeck-street, W.—Hon. Reg.

York City.—Asst. M.O.H., &c. £600.

York Maternity Hospital.—H.S. £250.

Births, Marriages, and Deaths.

BIRTHS.

BARCLAY.—On March 26th, 1925, at 2, Greenhead-road, Huddersfield, the wife of William Barclay, M.B., F.R.C.S. Edin. of a son.

CALWELL.—On 29th March, 1925, at 69, Holland Park-avenue, London, W. 11, to Maud, the wife of Dr. W. K. Calwell—a son.

ESLER.—On March 23rd, at Denholme, Datchet, Bucks, the wife of M. S. Esler, M.R.C.S., of a daughter.

GRANGE.—On March 24th, at Phœnix Lodge-mansions, Brook Green, W., the wife of F. A. Grange, M.C., M.B., B.S., of a son.

HAYMAN.—On March 26th, at Caister-road, Great Yarmouth, the wife of F. Keith Hayman, F.R.C.S., of a son.

PEAKE.—On March 18th, at Exeter, the wife of Captain H. G. Peake, Royal Army Medical Corps, of a son.

THOMPSON.—On March 25th, at The Avenue, Southampton, the wife of A. G. G. Thompson, M.D. Camb., of a daughter.

DEATHS.

MELVILLE.—On March 24th, following an operation at a London nursing home, Gordon Moncreiff Melville, M.D., of Ashley Lodge, Basingstoke, aged 42 years.

TAYLOR.—On March 22nd, at Alma-road, Clifton, Bristol, James Taylor, M.R.C.S. Eng., L.S.A.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

LEIGH INFIRMARY EXTENSION.—The governors have decided upon extensions of the infirmary which will involve a sum of about £26,000. The extensions include the erection of a new children's ward and a nurses' home.

THE Minister of Health has appointed Mr. H. W. S. Francis, O.B.E., Assistant Secretary, Ministry of Health, to the post of Receiver of the Metropolitan Common Poor Fund with effect from April 1st, consequent on the appointment of Sir Aubrey Symonds, K.C.B., as Secretary to the Board of Education. Mr. E. Tudor Owen, O.B.E., is appointed an Assistant Secretary to the Ministry.

Notes, Comments, and Abstracts.

DEAFNESS IN LITERATURE.

By Macleod Yearsley, F.R.C.S Eng.

THERE can be no doubt that, although it is open to debate whether blindness or deafness is the greater affliction, the former infirmity is, for purposes of charity, the more spectacular. The same holds good in literature apparently, for when, a short time ago, I made some investigation into the matter, I was surprised to find how meagre is the record. The reason is indicated in my opening sentence, and, in support of my contention that blind persons appeal far more eloquently to popular sympathy, I may quote a remark once made to me by my friend the late Mr. George R. Sims to the effect that when a dramatist wished to move his audience to tears he placed a blind character upon the stage, but when his object was to excite laughter he used one who was deaf. Yet deafness, depicted by the hand of a master, can be made as moving as blindness, as I hope to show presently.

The allusions to deafness which I have been able to find in literature are, save the occasional introduction of a deaf fool as comic relief, almost entirely confined to Boswell, Johnson, Scott, John Kerr, Dickens, and Thackeray among prose writers, to Chaucer, Shakespeare, and Hood among poets. There is also a passage on deaf-mutism of some merit, quoted as a chapter heading in "Peveril of the Peak," and ascribed by Scott to an old play, the authorship of which I have failed to discover. In reply to the question "Can she not speak?" a character answers:

> "If speech be only in accented sounds,
> Framed by the tongue and lips, the maiden's dumb;
> But if by quick and apprehensive look,
> By motion, sign, and glance, to give such meaning,
> Express as clothed in language, be termed speech,
> She hath that wondrous faculty; for her eyes,
> Like the bright stars of heaven, can hold discourse,
> Though it be mute and soundless."

Chaucer describes his Wife of Bath as deaf and states the cause:

> "But she was somewhat deaf, and that was scathe."

Her defect she owed to her fifth husband, who hit her on the head for tearing the book he was reading. The good wife began her matrimonial experiences early, since she says:

> "For, lordlings, since I twelve years was of age;
> Husbands at churché door I have had five."

Husbands had, indeed, become a habit, for she adds:

> "Welcome the sixté, when that ever he shall."

Shakespeare makes but two notable allusions to deafness, although deafness and dumbness are employed by him metaphorically no less than 39 times, while Milton uses deafness metaphorically but twice. In *Julius Cæsar*, Act i., Scene 2, the great Roman says to Antony:

> "Come on my right hand, for this ear is deaf."

In the Second Part of *King Henry IV.*, Act i., Scene 2, deafness is introduced with a more comic purpose in the meeting between the Lord Chief Justice and his Apparitors with Falstaff. The fat old reprobate tries to slink off, mindful of his last interview with the Justice, but the latter calls him back. To his page Sir John whispers aside, "Boy, tell him I am deaf," and the lad says to one of the Apparitors, "You must speak louder; my master is deaf," upon which the Justice, with reason, remarks, "I am sure he is, to anything good."

From Shakespeare to Tom Hood is a far and descending cry. The latter wrote a long poem of 811 lines, "A Tale of a Trumpet," describing the deafness of an old lady named, possibly for rhyming purposes, Dame Eleanor Spearing, who acquired a kind of demon trumpet. This poem is of peculiar interest to me as mentioning my relative, Dr. James Yearsley, who died in 1869 and was one of the first of the old London aural surgeons. The stanza runs thus:

> "In short, she was twice as deaf as Deaf Burke,
> Or all the deafness in Yearsley's work,
> Who in spite of his skill in hardness of hearing,
>   Boring, blasting, and pioneering,
>   To give the dunny organ a clearing,
> Could never have cured Dame Eleanor Spearing."

Boswell says little or nothing of Johnson's defective hearing, but mentions his visit to the deaf school in Edinburgh in the following words:

> "Near the end of his 'Journey,' Dr. Johnson has given liberal praise to Mr. Braidwood's academy for the deaf and dumb. When he visited it, a circumstance occurred which was truly characteristical of our great lexicographer, 'Pray,' said he, 'can they pronounce any *long* words?' Mr. Braidwood informed him they could. Upon which Dr. Johnson wrote one of his *sesquipedalia verba*, which was pronounced by the scholars, and he was satisfied. My readers may perhaps wish to know what the word was; but I cannot gratify their curiosity. Mr. Braidwood told me it remained long in his school, but had been lost before I made my enquiry."

The actual remarks made upon this visit by Johnson are to be found in the closing chapter of his "Journey to the Western Islands of Scotland," and are no small testimony to the efficiency of the oral instruction of the deaf in the Northern Kingdom a century and a half ago. The closing paragraph is, as Boswell would say, "truly characteristical."

> "It was pleasing to see one of the most desperate of human calamities capable of so much help; whatever enlarges hope will exalt courage; after having seen the deaf taught arithmetic, who would be afraid to cultivate the Hebrides?"

That Johnson was himself deaf in later life is shown by the remarks of Miss Reynolds in the Appendix of Wilson Crocker's edition of Boswell. Miss Reynolds (the great painter's deafness is well known) said that "to his defective hearing, perhaps, his unaccommodating manners may be equally ascribed." Here I may digress for a moment to note the deafness of other literary persons. It will be recalled that Harriet Martineau employed an ear-trumpet and that Herbert Spencer "tempted providence" by using ear-stoppers. Jean Jacques Rousseau was another sufferer. In his "Confessions" (Book VI.) he describes a sudden attack of vertigo, with loud head noises of four different kinds. "This internal tumult was so violent," he says, "that is has injured my auricular organs, and rendered me, from that time, not entirely deaf, but hard of hearing." When first attacked, the author of the "Social Contract" tried bed and a doctor, but not liking the treatment, which was, in accordance with the therapeutics of the time, excessively nasty, abandoned it after a short trial. "The beating of my arteries," he adds pathetically, "and the buzzing in my ears has never quitted me a moment during the 30 years which have elapsed since that time." Only those who have experienced the terrible infirmity of constant noises in the head can realise what the infliction means. Martin Luther suffered similarly, and considered them to be the voices of the Devil tempting him.

If Johnson's appreciation of Braidwood's work in 1773 be just and wise, so also is the opinion expressed by Dr. John Kerr regarding the same work a century later. The passage is in his "Memories Grave and Gay," but is too long for quotation. It speaks of his unqualified respect and admiration for the untiring patience and sympathy of teachers of the blind and deaf. Kerr also gives it as his deliberate opinion that of the two defects deafness is the more distressing.

> "It may be a matter of opinion whether to be blind or to be deaf and dumb is the greater calamity, but, as a question of education, of mental health and balance, I am quite convinced that the deafmute is the greatest sufferer. He is more difficult to teach and more isolated; a wider gulf than in the case of the blind separates him from continuous, interesting intercourse with his fellows."

He gives his reasons fully in his ensuing words and with his opinion I heartily agree. It is, indeed, the most justly-reasoned summary of the comparative disadvantages of blindness and deafness that I have met with and should be read by those unthinking persons who, without adequate knowledge of the subject, assert that they would rather be deaf than blind.

Among the masters of fiction it is curious that deafness appears as a prominent incident in the works of three only—Sir Walter Scott, Thackeray, and Dickens. It is, of course, true that one may stumble across a deaf character or two, here and there, introduced for the purpose of raising a laugh, or that, in certain books (which, however, can scarcely be described as "literature") characters have pretended to be deaf and dumb in order that they might overhear certain important disclosures without exciting suspicion. Fenella in Scott's "Peveril of the Peak," is an example of these, save that she is drawn by the hand of a master. In the modern instances I gravely doubt whether such simulated deafness could be sustained with success for any length of time. I have an indistinct recollection of a detective story in which the usual astute amateur detective learned lip-reading in order to run to earth his prey. The idea is ingenious, but lip-reading is by no means easy to learn when one has one's hearing intact. But these instances are beside the point. The most important character of this kind is the Fenella to whom I have just alluded. Her real name was Zara, and she was not deaf and dumb at all, although the reader is kept in ignorance of the fact until nearly the end of the book. What is interesting to us is Scott's description of her as seen by Julian Peveril, as she stood at the head of the steps leading to the entrance of the Castle of Holm Peel in the Isle of Man.

> "This little creature—for she was of the least and slightest size of womankind—was exquisitely well formed in all her limbs, which the dress she usually wore (a green silk tunic,

of a peculiar form) set off to the best advantage. Her face was darker than the usual hue of Europeans, and the profusion of long and silken hair, which, when she undid the braids in which she commonly wore it, fell almost to her ankles, was also rather a foreign attribute. Her countenance resembled a most beautiful miniature; there was a quickness, decision, and fire, in Fenella's look, and especially in her eyes, which was probably rendered yet more alert and acute, because through the imperfections of her other organs, it was only by sight that she could obtain information of what passed around her."

The passage is so framed as deliberately to deceive the reader and throw him off the scent. Fenella does not seem to have been the type of young person one would care to invite to the proverbial tea-party, although she had many accomplishments—needlework, pencil drawing, ornamental writing. But her ready wit and acute intellect were coupled with an irascible temper, haughtiness, and vindictiveness. Her miscellaneous attainments caused her to be regarded as a fairy changeling, to which her invariable habit of wearing green helped to contribute. She was able to carry on an adequate conversation by gestures, writing, and sketching, as is vividly portrayed in the account of her first meeting with the hero. Her deceit was ultimately detected by that astute monarch Charles II., who, having directed the Countess of Derby to get into contact with her pulse, then gravely announced that her lover had been stabbed; her scream and the acceleration of her pulse gave her away. Fenella was not an original creation, for Scott confessed that he had obtained the idea from Goethe's sketch of Mignon, in Wilhelm Meister's "Lehrjahre."

Lovers of Thackeray (and I must confess myself his devoted admirer) will call to mind how, in the twenty-fifth chapter of "The Virginians" he introduces the extreme deafness of the great Lord Chesterfield, who, oblivious to the identity of Mr. Harry Esmond Warrington seated close by at the ordinary, talks scandalously both of him and his worldly old aunt, the Baroness de Bernstein, for which he makes a dignified apology upon learning his error. In a later chapter allusion is made to the deafness of Sir Joshua Reynolds.

Charles Dickens seems to have been especially fond of portraying defectives such as Smike, Barnaby Rudge, Tiny Tim, and Mr. Dick. I think Hugh, in "Barnaby Rudge," was a defective too, but, as Sir Squire Sprigge has pointed out in his delightful "Physic and Fiction," it is in descriptions of mental disease that Dickens revels, and Squeers, his daughter Fanny, and Newman Noggs were just as mad as the poor, tormented Smike. It is not to be wondered at, therefore, that he should have introduced a deaf-and-dumb child into one of his stories. We may dismiss old Mrs. Wardle in "Pickwick," "the very old lady, in a lofty cap and faded silk gown," as a very ordinary character, introduced to excite amusement. His description of her is fairly true to nature—"like most people, she never seemed to calculate the possibility of other persons hearing what she said herself," a truism pointed out also by Thackeray in the instance alluded to, but in other words. Mrs. Wardle was much less deaf on the subject of a rubber of whist than any other; my Lord Chesterfield was even more addicted to play. Possibly cards may have a special appeal to the deaf, since their use does not require much conversation.

Of a different order is Dickens's introduction of deafness in another book, for in this instance it has a touch of genius. In the penultimate chapter of "A Tale of Two Cities" (in my humble opinion the finest of his works), Miss Pross has her hearing destroyed at one fell swoop by the explosion of Madame Defarge's pistol when she is struggling with that fury of the Revolution. The truth dawns upon the courageous woman as she hurries through the streets with Mr. Jerry Cruncher. "I feel," she says, "as if there had been a flash and a crash, and that crash was the last thing I should ever hear in this life." She cannot hear the sinister rumble of the tumbrils on their way to the National Razor. . .

> "'If she don't hear the roll of those dreadful carts, now very nigh their journey's end,' said Mr. Cruncher, glancing over his shoulder, 'it's my opinion that indeed she never will hear anything else in this world.'
>
> And indeed she never did."

Curiously enough, Dickens's masterpiece in pathetic writing, the description of Sophy in "Dr. Marigold," seems to have been missed or forgotten by many of his readers. Yet the story sold as a Christmas number 250,000 copies in the first week and was one of its author's most successful readings. Those who know the deaf child, as I do, cannot fail to be moved by it. Dr. Marigold was a Cheap Jack, who lost his little daughter Sophy. Meeting with a giant—"He was called Rinaldo di Velasco, his name being Pickleson"—he found that Rinaldo's master had a deaf daughter whom he ill-treated. Marigold bought her for a pair of braces, and named her Sophy after his own lost little daughter. There is a delightful description of how he set out to teach her:

> "You'd have laughed—or the rewerse—it's according to your disposition if you could have seen me trying to teach Sophy. At first I was helped—you'd never guess by what—Milestones. I got some large alphabets in a box, all the letters separate on bits of bone, and saying we was going to WINDSOR, I gave her those letters in that order, and then at every milestone I showed her those same letters in that same order again and pointed towards the abode of royalty. Another time I give her CART and then chalked the same upon the cart. Another time I give her DOCTOR MARIGOLD, and hung a corresponding inscription outside my waistcoat."

Patience and trouble, as usual, triumphed, and the description of his labours is, to my mind, one of the best things Dickens ever wrote. "We had our signs, too, and they was hundreds in number," explained the Cheap Jack. Sophy was an intelligent child and responded well.

> "When I sold of a night, she would sit in the cart unseen by them outside, and would give a eager look into my eyes when I looked in, and would hand me straight the precise article or articles I wanted. And then she would clap her hands and laugh for joy."

Marigold and Sophy went happily on together until she was 16, and then her protector felt that she should have better teaching.

> "So I took her hand in mine, and went with her one day to the Deaf and Dumb establishment in London."

It is difficult to read what follows without being touched by it. One can so well realise the sacrifice which the large-hearted Cheap Jack was making. "Teach her the most that can be taught her in the shortest separation that can be named." There is a world of pathos in that. Dickens often gives one a sense of exaggerated sentiment, of striving after effect, but to those who know the deaf and their education there is nothing of that here.

> "'Well,' says he, 'can you part with her for two years?'
> 'To do her that good,—yes, sir.'
> 'There's another question,' says the gentleman, looking towards her,—'can she part with you for two years?'"

Sophy was a grown woman when her adoptive father saw her again. One gathers that her education was nor on the oral system and, seeing that she did not come under a teacher of the deaf until she was 16, this is not to be wondered at. I am at a loss to know to what institution Marigold took Sophy. Lickens must have had some particular establishment in mind when he wrote the story and probably paid it a visit in order to obtain the necessary local colour. There is, however, no allusion to any such visit in Forster's "Life," nor in any of the Dickens letters. I have, nevertheless, a suspicion that it was the school, now occupied by the London County Council as a Deaf School, in the Old Kent-road.

TWINS.

To the Editor of THE LANCET.

SIR,—Prof. G. R. Murray's remarks in THE LANCET of March 14th, on the subject of twins, recall the fact that even in Europe there was current at some very early period a belief that the bearing of more than one child at a birth was the result of the mother's adultery. That conjugal infidelity on the wife's part was at one time punishable with death is a fact well established in both Roman and Celtic tradition. Such being the case, the superstition with regard to twin births was a source of considerable danger to the mother, and the lady's attempts to evade the consequence of her rashness form the subject of a great number of mediæval romances and folk-tales. The belief occurs in various connexions in the literature and popular lore of England, France, Italy, Spain, Denmark, Holland, and Germany, being especially common in German tradition. The importance of folk-lore in the history of civilisation and in ethnology is now admitted, and the frequency with which this belief recurs can leave little doubt that at some far distant period it was widely current among the peoples of Western Europe.

A number of stories dealing with this superstition have been collected by Dr. Doris Wright Barker, and in most of them the central incident is somewhat similar. A lady of high rank accuses a beggar woman of adultery because she has borne twins. The slander is always punished by the lady herself becoming pregnant and being delivered at one birth of two or more children. The number of children is usually two, seven, or nine, but in one of the Dutch versions it is 13, and in that related in all seriousness by Korner in his "Chronik" for the year 1300 it is 364! The details vary, but in all of the tales the birth of the children is regarded as reliable evidence of their mother's guilt, and in most cases she is afraid of, or is actually threatened with, death.

The story of most interest to modern readers is a German folk-tale, the "Stamm-Sage der Welfen," or the tribal legend of the Guelphs, which professes to explain the origin of the name Guelph (Welf) which, it will be remembered, was borne before the war by our own Royal Family. In this tale it is related that the wife of Isembard von Altorf urges the death of a woman who has given birth at one time to three children, on the ground that she is an adulteress. The following year the lady is herself delivered of twelve children, and terrified of the consequences of such a feat, persuades her attendant to drown all but one. The maid places the children in a bucket, but on her way to the river is met by the father who inquires the nature of her errand. She replies that it is "but to drown a few baggage whelps in the river." Isembard, however, investigates for himself, and having finally come at the truth of the matter, sends the children to be secretly nursed. When they are grown, he presents them to his wife, who duly confesses her guilt and is forgiven. In memory of the incident, the family received the name of "Whelp" or Guelph, which is still retained by their descendants.

It has been stated that among the negroes of Guinea a woman who has borne twins is held guilty of adultery and is put to death. It would be interesting to know whether the view still to be met with that the birth of twins is something of a social blunder is a last relic of this singularly cruel and foolish superstition.

I am, Sir, yours faithfully,

Leeds, March 25th, 1925. W. MURPHY.

THE LOCAL OPTION CONFERENCE.

To the Editor of THE LANCET.

SIR,—It is somewhat amusing to note the references in the newspaper press to the Local Option Conference held at Hoddesdon last week, in which it is variously described as a "secret" conference or conclave. Actually, it was a private conference of temperance delegates, who, for convenience sake, met at High Leigh, which is one of the houses provided for the accommodation of summer schools and similar gatherings.

What is of importance is that before the second conference is held, the committees, which are apparently to be set up for the purpose of exploring further the questions of compensation under a local option scheme and the options which should properly find a place in such a measure, may succeed in agreeing on proposals which will be approved not only by the temperance bodies, but by the great mass of the electorate. After all, it is the latter who count, and the temperance bodies must be prepared to sacrifice their cherished ideas as to the justice of a restricted form of local option in favour of proposals which will satisfy those who are outside the official temperance movement but yet hold the key to the situation.

The weakness of the temperance party is that in its proposals it is too prone to ignore the real situation and to imagine that what it considers right is also practicable. The genuine temperance reformer who desires to make progress will acquaint himself with the position and point of view of the average elector and frame his Bill accordingly on constructive lines, relying upon the forces of education and experience to secure further progress.

I am, Sir, yours faithfully,

Surbiton, March 26th, 1925. R. MORTON STANLEY.

TYPHOID FEVER ON A MILK FARM.

A REPORT from the Ministry of Health (H.M. Stationery Office, 2*d.*) deals with an outbreak of paratyphoid fever which occurred last September at Chorley. Dr. W. V. Shaw, for the Ministry, made an exhaustive inquiry into the epidemic. Sir George Newman, in a prefatory note, gives a summary of the report and adds some important comments. He states that the epidemic, comprising 52 cases, of which two ended fatally, was caused by milk infected with *Bacillus paratyphosus* B, derived from a farm in Chorley rural district. On August 7th, 1924, a case of the disease occurred in the family of the farmer and was duly notified to the public health department of the district. The acting medical officer of health visited the farm, and, it appears, consented to the patient being nursed at home. He took no steps to safeguard the milk-supply, although no less than 60 gallons per day were being sent from the farm for distribution in the borough. Further, no other visit was paid to the farm by officers of the rural district council until Oct. 1st, when the occurrence of the outbreak in the borough aroused suspicion respecting the milk from the farm in question. The prevalence of the disease in the borough of Chorley commenced on Sept. 10th, and it was found that each of the 52 patients had consumed milk from the farm at the time when members of the farmer's household were in an infective condition, as was conclusively proved, not merely on clinical grounds but as a result of bacteriological investigation. Of the eight members of the farmer's household no fewer than four had actually suffered from paratyphoid fever in addition to the original case. In the circumstances described by Dr. Shaw specific infection of the milk at the farm was almost inevitable. The patient, nevertheless, was allowed to remain at home throughout the course of her illness without any supervision on the part of officers of the local authority. No official inquiry was made to ascertain whether adequate isolation of the patient was being maintained, or whether secondary cases had occurred among other members of the household. Sir George Newman comments on the outbreak by saying that it was caused by failure on the part of the responsible officer concerned to appreciate the danger inseparable from the retention at a dairy-farm of a case of paratyphoid fever.

SUMMER-TIME.

SUMMER-TIME in France and Belgium comes into force on the night of Saturday-Sunday, April 4th–5th, and in this country on April 18th–19th. In consequence of earlier summer-time on the continent posting times in London for despatches to the continent from April 6th to 18th inclusive will be an hour earlier in the forenoon than at present.

FELLOWSHIP OF THE BRITISH EMPIRE EXHIBITION.

THIS Fellowship, of which the Prince of Wales is President, was founded in November, 1923, with the purpose of ensuring in the first place the full success of the British Empire Exhibition, and second, to encourage a "united family feeling" among the peoples of the Empire. The central committee hopes to extend the ranks of the Fellowship during 1925, and to maintain it as a permanent organisation to encourage trade and industry within the Empire. Membership enrolment forms may be obtained from the offices of the Central Committee, 16 Grosvenor-gardens, London, S.W.1.

AN INGENIOUS TRUSS PAD.

THE T. Beasley's Surgical Appliance Company of Faraday House, 10, Charing Cross-road, London, W.C., have submitted to us a hernia appliance which should obviate a great deal of the trouble and inconvenience which may be caused by an unadaptable pad. The pad is a pear-shaped rubber bag covered with leather, and by the aid of a small detachable inflating bulb any degree of resiliency can be given to it. The air-filled pad adapts itself to the part which it is intended to support, and is kept in position by webbing or rubber bands, the latter, of course, being useful for bathing, or in the bath where the appliance is permanently worn. The whole apparatus is easily washable, and the air-valves are so simple that there is little likelihood of their getting out of order.

SIGNED BULLETINS.

WE have received several communications arising out of the signing of bulletins regarding the health of distinguished patients, to which considerable point is given by the publication this week (see p. 727) of a detailed history of the last illness of President Ebert. There were reasons why no mystery should be attached to the circumstances of the death of the late German President, just as there are reasons for deploring from the historical point of view the lack of similar details concerning the death of prominent political persons. For 300 years ago the sudden or unexpected death of anyone whose activities as a statesman, or whose future opportunities as heir-apparent, might be prejudicial to a religious or political party, was attended by accusations of poisoning. Civilisation has left that sort of thing behind to-day, but it has a right to information as to the health of its leaders. Where the invalid is a member of the Royal Family the names of the medical men in attendance ought certainly to be affixed to what is a national message. Where again the patient is one who is holding or has held positions of undeniable national importance the same rule applies, and it is in accordance with this rule that the signed bulletins, with which the events of the last few weeks has familiarised us, have been in ethical order.

There can be no classification of important people in accordance with which it could be decided by any ethical committee when the health of some persons and not of other persons is a matter of such national importance that the public has a right to authoritative information guaranteed by signature. In the great majority of cases where undue publicity has appeared to be given to the names of practitioners, well known or otherwise, investigation has shown that the medical man in question had nothing to do with the unfortunate newspaper paragraph. The matter was the subject of considerable discussion by the General Medical Council during the winter session of 1922, when the difficulty of detecting what were real breaches of ethical conduct was recognised, though the existence of abuses was acknowledged and regretted.

Lettsomian Lectures

ON

WOUNDS AND OTHER INJURIES IN THEIR MEDICO-LEGAL ASPECT.

Delivered before the Medical Society of London

By Sir BERNARD SPILSBURY, M.B., B.Ch. Oxf.,
LECTURER IN MORBID ANATOMY AND HISTOLOGY, ST. BARTHOLOMEW'S HOSPITAL MEDICAL COLLEGE; HON. PATHOLOGIST TO HOME OFFICE.

LECTURE III.*

In the second lecture I described the characters of incised wounds and stabs, and indicated the means by which they are produced; examples were given of methods of distinguishing suicidal from homicidal wounding, and of different ways in which death followed in these classes of injury.

Architecture of the Skull.

Fractures of the cranial bones, when they are examined in their medico-legal bearings, are distinguished from other fractures by the difficulty in many cases of estimating the degree of force that caused them, and of determining its point of application and direction. This difficulty is the result of the complex physical problem presented by the skull with its contents, and by the inadequate information, in many cases, as to the circumstances in which the injury was inflicted. If, for example, the victim was knocked down by a moving vehicle there may be no information as to where the vehicle hit him, as to what part of his body struck the ground, and as to whether he was dragged or crushed by the vehicle as he lay upon the ground.

Scalp injuries often give valuable information as to the point of application of the force, the nature and shape of the striking surface, and sometimes of the direction in which a blow was delivered. Bruises and wounds in the scalp should be studied as to their size, distribution, and relation to fractures, and a wound, if it is undermined along one margin, will give information of the direction in which the force was applied. Thus, a man who receives a blow on the forehead and falls, striking the back of his head on the ground, producing a lacerated wound on the left side of the occipital protuberance, may be found to have a fissured fracture running forwards for some distance in the base of the skull from the wound in the back of the head. In such a case the fracture has clearly originated at the point of application of the force, and is due to the fall, and not to the blow.

Drunkenness predisposes to head injury on account of the general muscular relaxation, so that in falling, the head strikes the ground with greater violence. The skull is generally regarded as a fairly rigid bony case, containing a semi-fluid incompressible mass, and possessing a certain degree of elasticity. The case is of irregular form and of complicated architecture, and is a good example of the adaptation of structure to function. The vertex, which is exposed to direct violence, has a regular curved form and a stout structure, a buffer of cancellous tissue, the diploë, separating two tables of compact bone; the base, which is protected in great part from direct violence by muscles, and by the attachment to it of the structures of the face and neck, is much more lightly built, consisting either of cancellous tissue, with a very thin compact shell, the bone being hollowed out in places by air spaces, or of thin plates of compact bony tissue, and it owes its strength and rigidity to a very irregular form, being subdivided into three pairs of fossæ, each pair lying in a different plane, and separated from one another by buttresses of stouter bone, which extend down from the vertex. The anterior fossæ are fairly horizontal and slope upwards slightly at the sides, but the middle fossæ slope abruptly downwards to the foramen magnum, curving upwards again from its posterior margin; these fossæ are hollowed out on each side of the middle line. The base of the skull is weakened in places by large foramina.

The contents of the skull consist of a more solid tissue, the brain, and a fluid portion, comprising the cerebro-spinal fluid and blood. It is only by the sudden escape of some of its fluid content that the cavity of the skull can be actually reduced in size by forces acting on it from outside, and this is brought about by the escape of blood from the venous sinuses. The fibrous septa of the dura mater, partly dividing the cavity into three compartments, renders still more difficult the calculation of the physical factors concerned in the production of fractures.

The structure of the skull changes at different periods of life; in infancy, and again in old age, when the bones may become more brittle, the physical properties of the skull differ markedly from those of the adult. There are also modifications of structure which are peculiar to the individual, and in every case of fracture the texture of different parts of the skull should be observed. A fracture is easily produced by violence applied directly to the base of the skull; the relative weakness of the base explains the ease with which it is fractured by direct violence, and the frequency with which fractures starting near the junction of vertex and base pass downwards rather than upwards.

Pathological Conditions in the Skull in Relation to Fractures.

Pathological changes in the skull may greatly affect the formation and extension of fractures. Extreme thinness of the whole of the vertex of the skull is occasionally found at any age; the condition may be due to slight internal hydrocephalus or other pathological condition, producing increased intracranial pressure of long duration; no cause for the condition may be found. The following are examples of fracture produced in very thin skulls by slight causes.

An Australian soldier of uncertain age was walking on the slippery surface of a frozen road when he fell forwards on his hands and knees, and struck his head slightly on the ground, producing an abrasion on one eyebrow. He got up at once, apparently none the worse for the fall, and went to bed as usual. Some hours later he was found unconscious, breathing stertorously, and he died less than three hours afterwards. On post-mortem examination of the body there was no injury of the bone beneath the abrasion, although the skull was little thicker than paper, but three fissured fractures were found in the left middle fossa, radiating from a point slightly external to the foramen spinosum; the fractures did not extend beyond the limits of the fossa. The middle meningeal artery was injured at the central point of the fractures, and death was due to compression of the brain by a large extradural hæmorrhage.

In another case a girl, aged 6, was running in the street when her shoe twisted under her, and she fell on the edge of the pavement. She got up with help and seemed to be shaken. On reaching home she complained of pain at the side of the head. Two hours later she lost consciousness, her breathing became stertorous, her pulse-rate was reduced, and her right pupil became dilated; she died about eight hours after the accident. Upon examination a small bruise was found in the scalp a short distance behind the right ear; there was hæmorrhage into the temporal muscle beneath the bruise, and a fissured fracture was found in the skull; this started beneath the bruise and ran downwards and forwards for 2½ inches, terminating in the right middle fossa. The fracture gaped slightly, the middle meningeal artery was torn, and there was a fairly large extradural hæmorrhage. There was no intradural hæmorrhage, excepting a tiny bruise in the contre-coup position on the surface of the left cerebral hemisphere. The skull at the front and sides of the head was no thicker than paper.

Obscure conditions of local or general thickening of the skull will have the opposite effect. There is no doubt also that the structure of the skull may be modified by occupation, and the bones proportionately strengthened when continually exposed to such strain as that imposed by the carrying of heavy weights on the head; whilst racial differences, as in the negro, have also to be taken into account.

---

* Lectures I. and II. appeared in THE LANCET of Feb. 28th (p. 421) and March 7th (p. 480) respectively.

Sutures in Relation to Fracture.

A suture may divert a fracture; thus a fracture passing at an acute angle into a suture may run for some distance along it, opening the suture, then leaving it to continue in the adjacent bone in a direction parallel to its original course, or in an entirely different direction; when sutures are completely obliterated, as in old age, this modification will not be found.

An unusual example of a fissured fracture traversing sutures was found in a young man aged 23 who was struck a severe blow on the head and died from its effects in a few hours. He had a lacerated scalp wound on the right side of the back of the head; it was more than an inch long, ran transversely, and extended to the middle line $1\frac{1}{2}$ inches above the occipital protuberance. The upper margin of the wound was slightly undercut in the middle line, and there was considerable bruising around it. The skull was thin and brittle, especially at the sides. The right parieto-occipital suture was beneath the wound and was sprung from the middle line to its right extremity; from that point a fracture ran horizontally forwards through the squamous bone immediately above the ear, then turned upwards to the squamo-parietal suture, in which it ran forwards and then downwards to the base of the skull in the right middle fossa, where it entered the groove for the middle meningeal artery, along which it extended to the foramen spinosum. The middle meningeal artery was torn about $\frac{3}{4}$ inch from the foramen; the man died from an extradural hæmorrhage.

Fractures of the Skull.

Fractures of the skull are produced by the application of force directly to the vertex or base, but the base suffers far less frequently from direct violence. The anterior fossæ are occasionally fractured by blows reaching the roof of the orbit, or nose, the middle fossa through force acting through the mouth or pharynx, and the posterior fossa may be injured by force transmitted upwards by the spine, or through the upper part of the back of the neck.

An unusual example of fracture of the base of the skull by direct violence was that of a young man, who, when riding a bicycle, collided with a motor-car. He was profoundly unconscious on admission into hospital; he became delirious and died from respiratory failure 12 hours later. Shortly before death the right eye was protruded. At the autopsy there was a superficial lacerated wound along the right supra-orbital ridge, the eyelids were bruised on both sides, and there were slight abrasions on the left side of the face. The right eyeball was unruptured, but there was hæmorrhage in the posterior chamber. The orbital plate of the right frontal bone was fractured, a triangular piece about the size of a threepenny-piece being completely detached. The dura mater was torn over the fracture, and the fragment of bone was found in a mass of blood-clot immediately above its original position. Above the fracture the brain was lacerated, and a broad track, filled with blood-clot, extended from the laceration completely through the right cerebral hemisphere in an upward, inward, and backward direction; the corpus striatum was injured near its front end; the lower edge of the falx cerebri and the inferior longitudinal sinus were torn. There was superficial laceration of the left cerebral hemisphere on its inner surface in the same line. There was a collection of blood-clot, which had escaped from the sinus in the longitudinal fissure.

At the moment of collision the young man must have received a severe blow directly in front of the right eye, bruising the eyeball without rupturing it, and driving the eyeball with such violence against the roof of the orbit as to fracture the bone, and force the fragment through the right cerebral hemisphere as far as the middle line. The escape of blood from the tear in the longitudinal sinus pushed back the piece of bone, which was a very thin flake, along the track to the point where it was found.

Far more frequently fractures in the base are the result of the extension of fractures produced by violence applied to the vertex, the fracture starting at the point of impact on the skull, and running downwards in a line which is fairly straight, when allowance is made for difference of strength and irregularity of shape of the base; this line corresponds with, or is parallel to, the direction of the force. The following is a typical example of a simple fissured fracture of the skull caused by a fall:—

An elderly woman going downstairs was heard to fall; she was found unconscious at the foot of the stairs, and was bleeding from the mouth, nose, and ears; unconsciousness deepened, and she died a few hours after the accident. She had a lacerated scalp wound $2\frac{1}{2}$ inches long, and transverse in direction, in the left occipital region. Beneath the wound was a fissured fracture which extended downwards, forwards, and slightly inwards, in a straight line across the left posterior fossa and the pituitary fossa. There was superficial laceration of the left lobe of the cerebellum beneath the fracture, and contre-coup injury of the right frontal lobe and of the right temporal pole.

In another case a young woman was admitted into hospital for the treatment of a badly lacerated vagina produced during labour. She became strange in her manner, and a few days later, eluding the nurses, she escaped from the ward to the roof of the hospital, from which she fell a considerable distance, being picked up unconscious, and dying shortly afterwards. She had a contused lacerated wound $1\frac{1}{2}$ inches long immediately above and behind the right ear. Beneath the wound was a fissured fracture which extended across the base of the skull, the fracture bifurcating to enclose the right petrous bone, which was also traversed by a fracture through the tegmen tympani. The fracture then crossed the sphenoid behind the pituitary fossa, and passed in front of the left petrous bone to the junction of the base and vault; the skull was dense.

This fracture resembled the one most frequently produced by bilateral compression of the skull.

Fissured fractures often cross foramina; in one case a fracture which started at the occipital protuberance, as the result of a fall on the back of the head, ran downwards and forwards in the middle line to the foramen magnum; it continued its course in the middle line for another inch from the anterior margin of the foramen. Occasionally a fissured fracture starting near the junction of vertex and base will run through the vertex rather than downwards.

An instance of this was found in a man, aged 50, who was admitted into hospital in a comatose condition, with a head injury, the result of a fight; he died three hours later. He had a lacerated wound in the mid-occipital region, and on internal examination a fissured fracture extended from the wound forwards in the middle line, over the vertex to the root of the nose. The interparietal suture was opened up at the back; the superior longitudinal sinus was torn, and there was hæmorrhage around it.

A fracture may be found extending across the base of the skull between two points on opposite sides of the vault, which have been simultaneously compressed. The explanation of these double compression fractures is that severe pressure at two points reduces the distance between them, the incompressible contents distending the skull in other directions, especially at the equator, where the skull may burst open in the weakest part of its circumference—namely, the base, near the middle-line—the fracture extending towards the two points of compression.

A typical bilateral compression fracture was found in a young man who was knocked down and run over by a van, a wheel passing over his head. He was admitted into hospital deeply unconscious; there was much hæmorrhage from the right ear and weakness of the right side of the body. He died less than three days later without regaining consciousness. On examination abrasions were found on the right ear and behind it, and on the left side of the head and left cheek, the left eye being bruised. A fissured fracture extended transversely across the base of the skull through the middle fossæ and the pituitary fossa, running immediately in front of the petrous bones. On the right side the fracture also extended to the posterior fossa along the line of the inferior petrosal sinus. Death was caused by septic meningitis of the base of the brain, consequent upon injury to the wall of the sphenoidal sinus.

When very considerable force is applied over a small area of the vertex, a local fracture may be produced, which corresponds in form with the striking surface. Thus, the fracture produced by a penetrating stab with a sharp knife, or by the edge of a heavy sword, may exactly fit the part of the weapon which penetrated the bone. If the weapon has a thick blade and a wedge-shaped edge, as for example, a hatchet, a fissured fracture may extend for some distance from each end of the cut produced by the blade.

A very severe blow with a blunt weapon, such as the head of a hammer, may produce a local depressed fracture corresponding accurately, on the outer surface of the skull, with the striking surface of the weapon. But, as in the case of bullet injuries in the skull described in the first lecture, the extent of the fracturing of the inner table is always greater, and generally of more irregular shape. Occasionally the outer table will scarcely be indented whilst the inner table is markedly depressed. Very rarely the outer table is driven inwards, and the diploë crushed, without apparent damage to the inner table.

It may happen that a depressed fracture of unusual shape will enable the weapon to be identified.

A woman, aged 79, was found dead in her apartment, with serious injuries produced by a murderous assault ; a young man was charged with causing her death, and was convicted of murder. There were 17 lacerated wounds on the left side of the head, and two similar wounds near the right ear. There were three incised wounds on the front and right side of the neck. There were also bruises and lacerated wounds, and a number of cuts on the hands and fingers. Six depressed fractures were found beneath the lacerated wounds on the left side of the head ; three of the depressions were of the same size and shape on the outer surface, well defined and rectangular ; the other three were of about the same size, but were less regular in form. There was only slight extradural hæmorrhage beneath the fractures ; there was no intradural hæmorrhage and no injury to the brain.

In the murdered woman's room was a poker, the head of which was faceted at the sides, the facets being rectangular and corresponding exactly in shape and size with three of the depressed fractures. There was no doubt that this was the weapon with which the injuries on the head were inflicted.

The fracture produced by a stick, or a poker, when great violence has been employed is an elongated, gutter-shaped fracture. If the object producing the fracture is of small size, such as a pebble, it may be found embedded in the fracture. With rather less violence the same type of weapon will produce a less severe depressed fracture, from which one or more short fissured fractures extend. With still less violence a single fissured fracture of considerable extent may be found. The depressed fractures produced by weapons having a limited striking area, and many of the fissured fractures produced by these weapons, are compound, the soft tissues covering the bone being split open in the area of greatest compression. Fissured fractures of the base, laying open the sphenoidal or other sinuses, are also compound, and death may follow from meningitis, as in the case of double compression fracture already described.

When a large area of the head is subjected to considerable violence, as in falls on a level surface from a height, fractures of the skull may be local, but involve a larger area than those produced by small striking surfaces ; these are generally comminuted, and similar, but more extensive, fractures are produced by severe crushing injuries of the head. There may be little depression of the broken fragments, but fissured fractures generally radiate from the margin of the comminuted area ; these are also less frequently compound than depressed fractures.

In the following case a man, aged 42, was admitted into hospital in an unconscious condition, having fallen a distance of 60 feet ; he died an hour after admission. At the post-mortem examination there were two irregular lacerated wounds of the scalp, one over each parietal bone. The top of the skull was smashed into about a dozen pieces, the fractures appearing to radiate from the right parietal eminence. There was also a transverse fracture of the base, through the pituitary fossa and the petrous bones. The cribriform plate and the orbital plates of the frontal bones were also fractured, the right orbital plate being comminuted. There was meningeal hæmorrhage over the whole surface of the brain, but there was only slight contre-coup injury of the right frontal and temporal poles and of the lower surface of the right lobe of the cerebellum.

The squamous portions of the temporal bones are generally thinner than the rest of the vertex ; the diploë may be absent, and the two tables united to form a thin plate of compact bone ; a similar structure is sometimes present in the posterior fossæ below the level of the lateral sinuses. Less violence is necessary to produce fractures in these areas.

When the effects of the passage of bullets through the head were described, I pointed out that amongst the bursting effects it was not infrequent to meet with isolated fractures in the orbital plate of the frontal bone, the cribriform plate, and in the tegmen tympani, when these areas were unusually thin. The bone then consists of a delicate plate of compact tissue, and the fractures are often comminuted. Fissured fractures which extend to the base are likely to be comminuted, as they cross such areas as these. But contre-coup fractures are occasionally seen in these areas, a violent blow, for example on the occiput, driving the brain against the inner surface of the skull with such force as not only to bruise or lacerate the frontal and temporal poles, but to produce fractures of thin orbital plates, the injury being followed by hæmorrhage into the eyelids if the patient survives for a sufficient length of time.

Contre-coup fractures were found in a man, aged 74, who was crossing the street when he was knocked down by a cyclist. He managed to walk home with assistance, but he gradually lost consciousness later, and died about 20 hours after the accident. He had two superficial lacerated wounds on the left side of the back of the head, neither passing completely through the scalp. There was extensive bruising round these areas and around the left eye, where the bruise showed some colour changes. There was slight bruising of the right upper eyelid. The base of the skull was unusually thin, especially the orbital plates. A fissured fracture was found beneath one of the scalp wounds, at a point $1\frac{1}{4}$ inches to the left of the middle line and $\frac{3}{4}$ inch above the level of the occipital protuberance ; the fracture extended downwards, forwards, and slightly inwards, crossing the left posterior fossa, and ending at the petrous bone. There was another fracture an inch long in the right orbital plate, running forwards and outwards, and a third fracture in the left orbital plate.

The last of these, and probably the one in the right orbital plate, are examples of contre-coup fracture of the skull produced by violent impact between the brain and the skull at the moment when the back of his head struck the ground, the very thin bone giving way without causing injury to the brain. When the skull is extremely thin all over, the jarring due to a slight blow or fall may produce a fracture in an area at a distance from the point of application of the force, which does not coincide in direction with the force, and which is not in the contre-coup position. The groove for the middle meningeal artery and its branches may be unusually deep and its floor may consist of very thin bone ; a fracture may arise in one of these grooves and may extend along it and its branches without involving any other part of the skull. The middle meningeal artery is likely to be torn, and an extradural hæmorrhage produced as a result of such an injury. The following case illustrates this type of injury :—

A man, aged 40, fell in the street, striking his head on the pavement ; shortly afterwards he complained of pain in the head, rapidly lost consciousness, and died about five hours after the accident. On examination of the body a small bruise was found in the scalp 2 inches above the left ear, where his head had struck the ground. The skull was thin, especially at the sides, and was deeply grooved for the middle meningeal arteries. There was a V-shaped fissured fracture in the left middle fossa, the apex of the V being in the groove for the middle meningeal artery, and the two limbs of the fracture extended along the grooves for the main branches of the artery. The artery was torn at the apex of the fracture, and there was a large extradural hæmorrhage spreading from the injured vessel upwards to the vertex. There was no intradural hæmorrhage and no injury to the brain, and the fracture of the skull was confined to the grooves for the artery.

Contre-coup Injury to the Brain.

When we consider how contre-coup injury of the brain is produced it is perhaps incorrect to regard the contents of the cranium merely as a semi-fluid mass, for the brain has a defined form, and tends to move as a whole in response to a force applied at one point. If, for example, a heavy fall on the back of the head produces a lacerated wound on the right side of the occiput, and a fissured fracture extending across the pituitary fossa, it will frequently be found that whilst the opposite point in the brain, in this case the left frontal pole, shows contre-coup injury, less marked injury is frequently seen at the right frontal pole and frequently at both temporal poles.

Contre-coup injury to the brain varies in degree. Sometimes the damage is confined to a few small vessels in the pia mater; in other cases there is superficial bruising of the brain, and in more severe injuries the bruising extends deeply, and may be followed by considerable hæmorrhage into the substance of the brain. Occasionally contre-coup injury to the brain is produced by its projection against one of the fibrous septa of the dura mater, especially the falx cerebri, the injury being found on the mesial aspect of the cerebral hemisphere on the side on which the blow has been delivered.

When there are unusually marked variations in the thickness of the different parts of the skull, a fissured fracture, starting at the point of application of the force, and extending for a certain distance, may end in fairly thick bone, and a separate fracture may be found in very thin bone in the same line, the two being separated by an area of intact bone. Of this the following is an example:—

A young man fell down 17 stone steps; he was found unconscious and was admitted into hospital in a comatose condition, remaining so until death 13 hours later. He had a small superficial abrasion on the back of the head, midway between the left ear and the occipital protuberance, with a large bruise around the wound. A fissured fracture started beneath the abrasion and ran forwards through the left posterior fossa, to end close to the margin of the foramen magnum. A separate fracture in line with this one traversed the orbital plate of the right frontal bone, which was very thin, from behind forwards and slightly outwards. There was hæmorrhage into the orbital tissues, and deep laceration and bruising of the lower surface of the right frontal lobe, extending into the lateral ventricle, and extensive superficial bruising of the right temporo-sphenoidal lobe.

Intracranial Hæmorrhage without Fracture.

It occasionally happens that a person receiving a blow upon the head dies from extradural hæmorrhage due to rupture of the middle meningeal artery, without fracture of the skull, which in these cases is generally abnormally thin; the hæmorrhage is probably due to laceration of a branch of the artery, produced by sudden deformation of the skull. The following case illustrates this condition:—

A youth of 16 was admitted into hospital as the result of an accident, the nature of which is not recorded. He was deeply unconscious, and died on the following day. On examination of the body there were superficial abrasions on the left forehead and cheek, and on the left side of the chin. The skull was very thin, and was excavated on the inner surface by the cerebral convolutions. The grooves for the middle meningeal arteries were also deep. There was a large extradural hæmorrhage on the left side over the middle meningeal artery; the injury of the vessel could not be located, and a careful search failed to reveal a fracture of the skull. There was no injury to the brain and no intradural hæmorrhage.

Occasionally, also, a fall produces injury of the brain, sometimes in the contre-coup position, terminating fatally, without producing a fracture of the skull.

Thus, a man, aged 50, fell on the back of his head from a ladder; he was comatose on admission, but there was no bleeding or vomiting; coma gradually deepened and he died six days after the accident. On examination of the body a lacerated wound 1½ inches long was found in the right occipital region, and there was extensive bruising around the wound. There was no fracture of the skull, but there was extensive superficial laceration of the brain at both frontal poles, and much subdural hæmorrhage over the greater part of the surface of the brain.

In another case a man, 43 years of age, fell 20 feet, his face striking the ground. The injury to the brain was at the occipital poles and along the posterior borders of the cerebellar hemispheres; the skull in this case was thick and dense, and was unfractured.

Injuries to the Head in Infants.

In infancy the skull differs markedly in structure from the adult form, to which it approximates only after the second year. Instead of having a complete and rigid bony wall, the cranial cavity is bounded by bones which in the base are joined to one another by cartilage, but in the vertex are separated by fibrous septa, which in places are fairly broad. The bones of the vertex are pliable, and can be bent to a considerable extent without fracturing. The skull can therefore undergo considerable alteration in shape, under the influence of pressure, without being fractured, or the brain injured.

This is seen in the moulding of the head which occurs during labour. If considerable force is applied to the vertex of the skull over a limited area it produces a local indentation which, if very marked or sudden, may fracture the skull and may even tear the dura mater beneath the fracture. The parietal bone is the one most frequently injured, the fractures generally crossing or radiating from its eminence. The presence of fibrous septa tends to limit a fracture to the bone in which it arises, but if pressure or force is applied near the junction of two or more bones, indentation of the head may lead to the fracturing of adjacent bones, the fractures not infrequently running in different directions in contiguous bones.

This condition was found in a new-born child, whose dead body, wrapped in paper, was found under the seat of a railway carriage; the mother was charged with causing its death. There was a slight abrasion on the right temple, bruising of the right conjunctiva, and much bruising in the scalp over the whole of the right side of the head. In the right parietal bone two fissured fractures radiated from the eminence, in the form of a V, to the posterior and inner margins of the bone, and two other fractures extended from the inner margin towards the eminence; a fracture 1 inch long ran horizontally across the middle of the front of the head, involving both frontal bones. There was slight extradural hæmorrhage beneath the fractures in the parietal bone, and a little free blood over the whole surface of the brain, but no injury of the brain.

The following case is an example of a very severe injury of the skull:—

An infant, 4 months old, was brought to the hospital deeply unconscious, with dilated pupils; a depressed fracture was felt on the right side of the head; death occurred the following day. The child was stated to have been found unconscious, having apparently fallen from a chair. On examination of the body there was severe hæmorrhage in the scalp over the whole of the right side and back of the head. A fissured fracture traversed the right parietal bone parallel to and 1½ inches from the middle line; the fractured edges were separated by half an inch in the centre, the dura mater was torn, and brain matter protruded. The fracture also extended in the same line through the right frontal bone, almost to the margin of the orbit, and at the back it extended into the occipital bone, curving round and crossing the middle line half an inch above the occipital protuberance and terminating one inch to the left of the middle line. The brain was lacerated along the whole area of the fracture, the injury being most severe beneath the fracture in the parietal bone. There was no contre-coup injury of the brain. Such a severe injury could not have been produced by a fall from a chair, and was probably the result of a very severe blow with a stick or similar object.

In infants fractures of the vault do not often extend to the base on account of the absence of rigidity, and for the same reason double compression fractures of the base are not seen. By the age of 2 years, however, the skull has developed a fairly rigid structure and the types of fracture seen in the adult may then be found. The following case is an example:—

A child of 2 years was admitted into hospital deeply unconscious, having fallen upon its head. It remained in this condition until death 48 hours later, having developed no nerve palsies or other localising signs. The only injuries were in the head; there was hæmorrhage into the eyelids on both sides, and blood in the right ear. There was a fracture completely across the base of the skull, at the junction of the anterior and middle fossæ, the fracture also extending upwards into the vault on the right side; the cribriform plate was disorganised. Another fissure extended backwards through the right middle fossa to the petrous bone. There was no hæmorrhage within the skull, and no apparent injury to the brain.

In infants injury to the brain is found only in the more severe cases, and then usually along the line of the fracture; contre-coup injuries are not found, the earliest age at which I have seen them being at 2 years and 8 months, in a boy who was being carried across the road by a brother, when they were knocked down, but not run over, by a motor-car. The boy was conscious when he was picked up, but became restless during the night, had screaming attacks and fits, passing into a condition of coma, and died 24 hours after the accident. There were abrasions and bruises on his forehead in the middle line, and a fissured fracture, which started in the middle line of the forehead and ran backwards through the base, traversing the cribriform plate and terminating in the pituitary fossa. In addition to slight bruising of the frontal poles there was slight contre-coup bruising along the posterior borders of the lateral lobes of the cerebellum. There was only slight meningeal hæmorrhage.

Another striking feature of head injuries in infants is the very slight amount or even absence of meningeal hæmorrhage, except in those cases in which the brain is severely injured; death from concussion of the brain is relatively more frequent in children than in adults. Owing to the yielding character of the skull, the lacerated scalp wounds, so common in the more severe injuries of the head in adults are not found, excepting in cases in which the head is severely crushed or the scalp torn against a projection.

Complications of Fractures.

The intracranial effects and complications of fractures may appear either immediately or after a variable interval of time; occasionally they only become manifest a long time after the injury has been inflicted.

Of the immediate effects concussion is the principal, and is responsible for the unconsciousness which supervenes instantly in many cases of fracture of the skull. Death may be due to concussion, no gross change being found in the brain, except a little blood in the cerebro-spinal fluid of the lateral ventricles. Occasionally death occurs rapidly from hæmorrhage into the substance of the brain as an immediate effect of the injury; this is generally the result of damage to a vital part of the brain, such as the basal nuclei, the pons, or the medulla.

More frequently death is due to intradural hæmorrhage resulting from injury to the surface of the brain, the injury being immediately beneath the area of application of the force, or in the contre-coup position. The degree of laceration of the brain determines whether the hæmorrhage is limited to the sub-arachnoid tissue, or escapes into the subdural space, where it accumulates in dependent areas. When the brain is badly injured massive hæmorrhage may develop in the substance of the brain, extending even into the lateral ventricles.

Extradural hæmorrhage is responsible for death in a certain proportion of cases of head injury; it is generally the result of a fracture crossing the middle meningeal artery, but it may be produced by laceration of the lateral or other venous sinuses, the time between the infliction of the injury and the onset of symptoms being longer when the hæmorrhage is from the vein. Septic infection of the meninges develops in a certain proportion of cases of compound fracture of the skull, principally in those which cross the base and open one of the accessory air-sinuses, but septic infection of the scalp at the site of injury may extend through a fissured fracture to the meninges. Brain abscess is an occasional complication of fracture of the skull.

Of the remote effects of fracture of the skull it is more difficult to speak with certainty. We occasionally meet with undoubted examples of localised tuberculous infection of the brain, following upon injury to the head, in those who have an active focus of the disease in the body. The tumour-like masses are found in the superficial part of the brain beneath the injured area, or in the contre-coup position. Brain injury may determine the settlement of syphilitic lesions, though the evidence for this is less conclusive. In the case of true neoplasms we undoubtedly meet with examples of glioma, and endothelioma, developing in the subjects of previous severe injury of the head, and in some cases showing a similar relationship to the site of the injury, developing, that is to say, either immediately beneath the injured area or in the contre-coup position.

Injury to Intracranial Arteries.

Lastly, injury to the arteries within the skull may give rise to remote effects. An artery may be crushed and injured by sudden pressure of the brain against the skull, or may be stretched and torn by a violent blow upon the head. The injury, if it does not result in immediate rupture of the artery, may be followed by the development of an aneurysm. A history of previous severe head injury is found in some cases of cerebral aneurysm, rupture occurring either a few weeks, or some years, after the injury, or the aneurysm is found in a person dying from another cause. The anterior cerebral arteries at their commencement appear especially liable to develop aneurysm from trauma, death resulting from rupture into the frontal lobe. The injury in these cases is frequently a severe blow upon the top of the head producing unconsciousness at the time. The following cases illustrate the association of cerebral aneurysm with previous injury:—

A man, aged 64, died from acute intestinal obstruction, produced by the passage of a coil of small intestine through an opening in the omentum. At the post-mortem examination an aneurysm about the size of a pea was found in one of the anterior cerebral arteries, close to its origin; the aneurysm was unruptured, and had a fairly thick wall. There was an indurated yellow area in the brain immediately above the aneurysm, the result of previous injury and hæmorrhage. There was some senile atrophy of the brain, with dilatation of the ventricles, and slight atheroma of the cerebral arteries, but there was no indication of a previous fracture of the skull and no evidence of syphilis in any part of the body. On inquiring into the man's history it was found that 20 years previously he had received a severe blow on the top of the head when he was at work. He was rendered unconscious, and was incapacitated for some time. He then became insane, was in an asylum for three months, but made a complete recovery, and had no mental abnormality afterwards, nor had he complained of his head since that time.

It is evident from the after-effects that this man had received a very severe injury to his head. The close relationship anatomically of the aneurysm and the injured area in the brain is suggestive of their both having been produced by the blow.

The next case shows a much closer relationship in time between the injury to the head and death from a ruptured cerebral aneurysm.

An apparently healthy man, aged 38, was a caretaker in a factory; in the course of his night round he was passing through a doorway when several heavy boxes, each weighing 13 lb., fell from a shelf upon his head. He was found in a dazed condition, and had a slight abrasion on the right side of the top of the head and a lacerated wound on the right ear; he complained of a strange feeling in the head. Shortly after he had pains in the head and attacks of vomiting, for which he was treated medically and was later sent to hospital, where the Wassermann reaction was found to be strongly positive. His eyesight became bad, but improved for a time under treatment, and no optic neuritis was found. The pains in the head becoming much worse, he was sent to an infirmary, where he suddenly lost consciousness and died in a few hours. Death occurred rather more than five months after the accident. On post-mortem examination a large recent hæmorrhage was found in the substance of the right frontal lobe of the brain; there was no appreciable meningeal hæmorrhage. On the right anterior cerebral artery, close to its origin, was an aneurysm about the size of a small pea, which had ruptured into the cerebral hemisphere. The arteries of the brain were otherwise healthy, and there was no indication of syphilitic disease in any part of the body. On microscopic examination the wall of the aneurysm consisted of fibrous tissue infiltrated with blood, but a small artery close to the aneurysm showed some endarteritis. Although syphilis cannot be excluded as a factor in the production of the aneurysm, the development of head symptoms immediately after the accident in a man who was apparently perfectly healthy, and their continuance until the time when he died of a ruptured aneurysm clearly indicate, in my view, a relationship between the formation of the aneurysm and the blow upon the head.

An even closer association with injury is seen in the following case:—

A young man, aged 22, who was said to be perfectly healthy, slipped and fell in the street, and lost consciousness for about five minutes. He recovered and went home, where he said he had ricked his head. He was never well after the accident, complaining of pain in the head; he had frequent vomiting attacks and suffered from sleeplessness; his vision also became impaired. Fourteen days after the accident he had what appeared to be a fainting attack; four days later he became unconscious immediately after he went to bed, and died three hours afterwards, having had attacks of vomiting and frequent fits during that time. On post-mortem examination he was a well-nourished, muscular man. There were no external injuries. On opening the head a saccular aneurysm was found on the left anterior cerebral artery, close to its origin; the aneurysm had ruptured into the left frontal lobe and had burst into the lateral ventricle, all the ventricles of the brain being filled with blood. There was a little meningeal hæmorrhage between the frontal lobes, and more around the pons and cerebellum. There was no brain disease; the cerebral arteries were otherwise healthy, and no disease was found in the body. There were no indications of syphilitic or tuberculous disease on microscopic examination of the wall of the aneurysm.

In this case there can be no reasonable doubt that the formation of the aneurysm and its rupture were due to the fall.

SUMMARY.

For this lecture I have analysed 216 fatal cases of fracture of the skull, and I have endeavoured to obtain from them any information bearing upon the conditions which contributed to their production.

The dominating feature which emerges from such an analysis is the profound influence exercised by the structure of the cranial wall upon the effects of all but the most severe forms of violence applied to any part of the skull. The most marked contrast is between the fractures of infancy and those found in the adult form, but even in the adult striking individual discrepancies occur; some of these, as I have attempted to show, are explained by anatomical peculiarities, but many fractures will remain unexplained until we are able to assess with greater accuracy the complex physics of the skull.

CONCLUSION.

At the beginning of the first lecture I stated that it was impossible, in the time at my disposal, to give a complete account of the subject which I had selected —"Wounds and Other Injuries in their Medico-legal Aspect"—and I undertook to give you instead the results of my experience. Many gaps must be bridged in this method of treatment, whilst certain features are strongly, even perhaps over, emphasised in an attempt to extract from a multitude of facts the governing principles. The cases quoted in the lectures are intended to illustrate the text, and to bring into relief, in each example, some one point which I regard as of importance. The interpretation placed upon the facts is generally an amplification, rather than a contradiction, of accepted doctrine.

ABERDEEN HOSPITAL FOR SICK CHILDREN.—For more than a generation the buildings of this hospital have been unsuitable and the accommodation inadequate. It has now been decided to erect a new hospital upon a site paid for by Mr. and Mrs. Herbert Taylor, of Aboyne, at a cost of £110,000, of which £66,000 is already available.

Goulstonian Lectures

ON THE STUDY OF

GASTRIC FUNCTION IN HEALTH AND DISEASE.

By JOHN A. RYLE, M.D., F.R.C.P. LOND.,
ASSISTANT PHYSICIAN AND LECTURER ON MEDICAL PATHOLOGY, GUY'S HOSPITAL.

(Concluded from p. 705.)

LECTURE III.

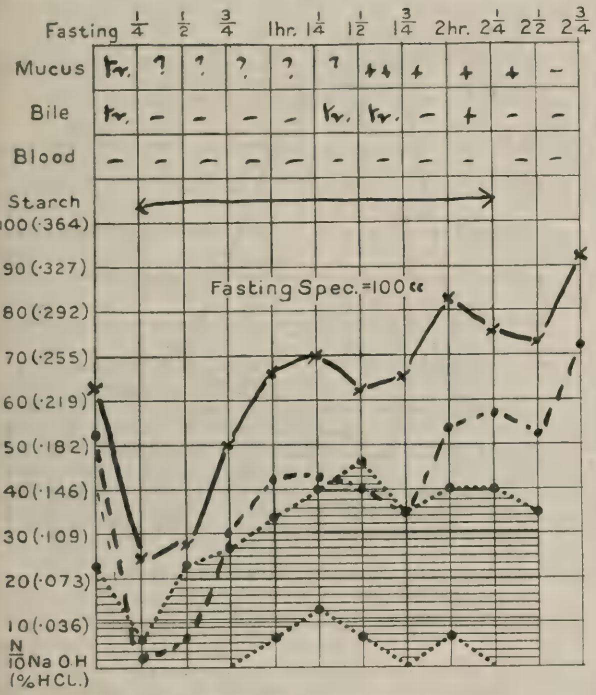
PART II.

GASTRO-JEJUNOSTOMY AND ITS SEQUELÆ.

OUR burden of responsibility in the case of dyspepsias following surgical intervention is necessarily greater than in the case of the original dyspepsia, and unfortunately the secondary dyspepsia is often more resistant to treatment than the primary disease. Only by a systematic study with clinical, radiographic, and chemical methods, of cases destined for gastro-jejunostomy, or in which a gastro-jejunostomy has already been performed, can we hope to elucidate the problems associated with this valuable operation and to explain the failures which still follow it in a sufficient percentage of cases to give cause for concern.

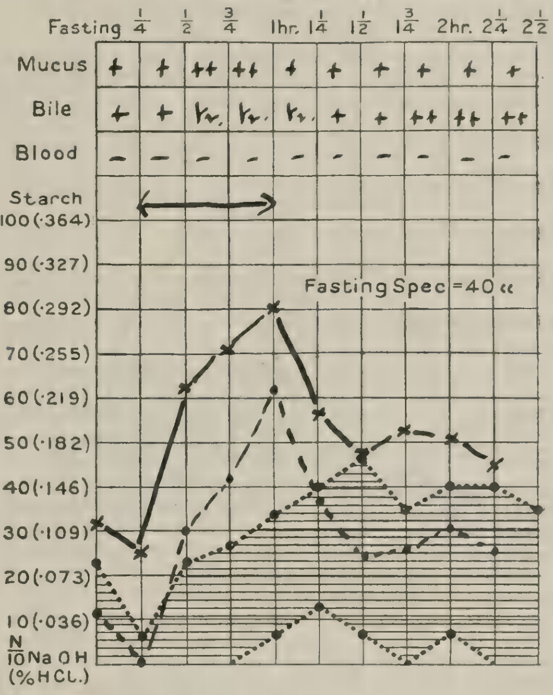
The faults and complications of gastro-jejunostomy include: (1) a too patent stoma, (2) a too narrow stoma or a mal-adapted loop with a "vicious circle" effect, (3) an improperly placed stoma, (4) ulceration at or near the stoma, (5) stenosis of the stoma secondary to ulceration, and (6) in the case of gastric ulcer, a failure to promote healing or a recurrence of the original lesion. Some of these errors and complications are theoretically, though not always in practice, avoidable; others are difficult to avoid. It would be entirely outside my province to refer to questions of technique, but there is one general principle which has not, I think, been sufficiently observed and upon which some of my previous observations have a distinct bearing. Briefly the principle is this: *That no attempt should be made to circumvent mechanically a lesion which is producing no considerable mechanical disturbance of function.* "Considerable mechanical disturbance of function" is nearly always associated in one way or another with the behaviour of the pylorus and its influence upon emptying rate; it need not necessarily be held to imply demonstrable organic narrowing of the pylorus or duodenum or indisputable delay. A reference to the history of gastro-jejunostomy will help to bear out my meaning. The operation was originally performed for pyloric obstruction due to growth, and was later employed in pyloric stenosis. So remarkable was the relief afforded in these conditions, for which it still remains the operation of choice in most cases, that it was next applied (still with some reason and often with success, because of the common association of "pyloric spasm" or "functional stenosis") to the treatment of non-obstructive duodenal ulcers of old standing; and then for no adequate physiological reason to non-obstructive duodenal ulcers of recent origin, and to chronic ulcers of the lesser curvature. The results of the operation are increasingly less good and the percentage of recoveries increasingly smaller as the condition treated becomes more remotely unlike the condition for which the operation was originally devised. I believe it will be in accordance with general experience when I say that in chronic duodenal ulcer the results are better the more nearly the disturbance of function which has been produced approximates to the disturbance present in organic stenosis. Even if no pathological degree of delay is demonstrable by ordinary means, a case with deficient or low normal motility is more likely to respond well to gastro-jejunostomy than one with increased motility; or, in terms of the test-meal, a case with a steadily climbing curve is more likely to give a good result than one with a high abrupt peak of acidity and rapid evacuation of the gruel. Whether the operation of gastro-jejunostomy performed for a chronic duodenal ulcer is successful or not in other respects, it generally results in healing of the original ulcer; this is due in the main to simple mechanical rest. But it has also been claimed that one of the principal aims of the operation is to produce a reduction of acidity by allowing a free entry of the duodenal secretions into the stomach. In practice the operation fails to achieve this in a considerable percentage of cases and the acidity may even be higher after the operation than before. In can achieve a reduction of acidity. The emptying-rate is already too rapid and the hypertonus present in such cases must throw a great strain upon the anastomosis. It is most unlikely that neutralisation of acidity will occur in cases of this kind and the conditions are ideal for the production of secondary ulceration. With a climbing curve as in Chart 20 A, however, and a normal rate of emptying the operation offers a better prospect of success. Even in this case the hypertonus of the organ was too great to permit of an efficient reduction in acidity during the digestive phase. Charts 21 A and B are from a case with well-marked hypotonus in which an efficient neutralisation was achieved. There is a greater liability to gastro-jejunal ulcers in young adults and in cases with a short dyspeptic history or recent hæmorrhage; this liability may be related to the fact that hypertonus is a more common attribute of youth, and that with recent ulceration there has been no time for the development of secondary loss of gastric tone. The cases in which a really satisfactory reduction of acidity results are those in which gastric tonus before the operation is normally low or has been lessened by prolonged fatigue; the efficient reduction of acidity in gastric ulcer and old-standing pyloric stenosis supports this contention. Apperly[20] attributes high acidity persisting after gastro-jejunostomy to defective reflux forces in the duodenum and jejunum and argues that persistent hypertonus is not a sufficient explanation because it was not always radiographically demonstrable in his cases. Whether the fault be in the stomach or the jejunum the rapid emptying after gastro-jejunostomy, if accompanied by an excess of intra-gastric over intra-jejunal tension, must tend to counter-balance the neutralising effects of artificial reflux.

CHART 20 A.



Duodenal ulcer. Climbing curve.

CHART 20 B.



Same case as 20 A after gastro-jejunostomy.

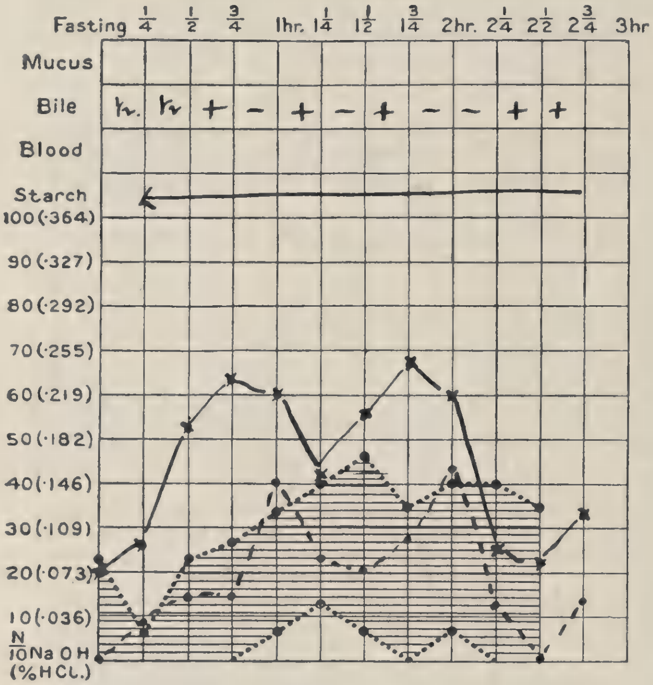
Hunter's[12] series of 40 cases of duodenal ulcer, pyloric ulcer, and ulcer of the body, in which 19 had a simple gastro-jejunostomy and 21 gastro-jejunostomy combined with occlusion of the pylorus, the free acidity "remained high" in 32 per cent., became higher in 23 per cent., and was abolished in 45 per cent. of cases. Sherren[13] has recently stated that "We have yet to learn what is the cause of failure to reduce gastric acidity by gastro-jejunostomy." I believe that the causes of failure to reduce acidity are not really far to seek, but it is evident that we require to know more about the conditions obtaining before the operation than the mere degree of acidity at one hour and the nature and situation of the lesion—information with which the surgeon is sometimes content. The most important additional items of information required are: (1) The rate of emptying of the stomach, and (2) the degree of tonicity present. *The quicker the rate of emptying and the greater the hypertonus the greater will be the liability to persistent hyperacidity. The slower the rate of emptying and the closer the approximation to a condition of hypotonus the greater will be the probability of efficient neutralisation.* The fractional test-meal gives valuable direct information in regard to emptying time and indirect information, as judged by the character of the curve of acidity, in regard to tonus. In the presence of an abrupt peak of acidity and rapid emptying, as shown in Chart 14, it is difficult to see how gastro-jejunostomy

In the light of modern experience it seems fair to insist that no gastric surgery, other than urgent surgery, should be undertaken for the relief of symptoms due to an active ulcer without a preliminary fractional gastric analysis as well as a radiographic examination. *The most important contra-indications to gastro-jejunostomy are a short history, a well-marked hypertonus, a high abrupt curve of acidity, and* *rapid emptying. The most reasonable indications for operation, apart from obvious stenosis, are a long history, a subnormal tonus, a slowly climbing curve, and slow emptying.*

A consideration of the cases described hereunder and of their test-meal findings may serve to indicate the utility of gastric efficiency tests in assessing the suitability of cases for operation and in studying the post-operative dyspepsias. In citing cases in which operation failed to give relief, or produced new symptoms, I would not have it thought that it is my intention to belittle the achievements of abdominal surgery. On the contrary, I believe that the advancement of our knowledge of the irritative and mechanical dyspepsias owes more to surgery than to any other branch of our art.

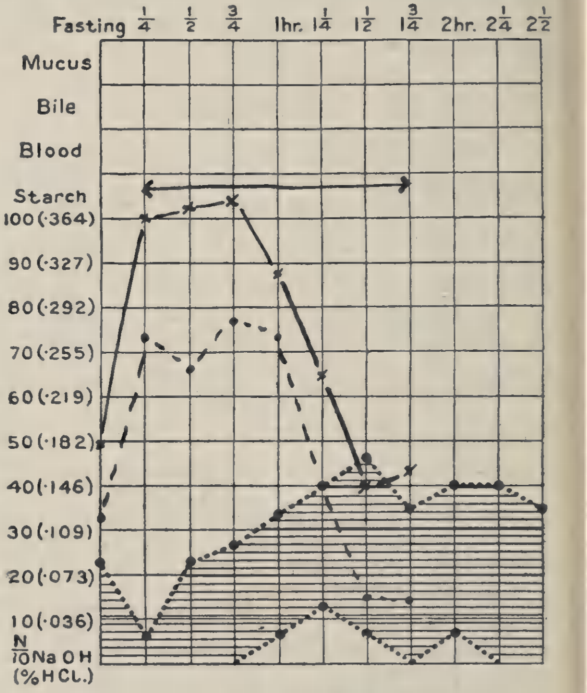
Charts 20 A and B are from a case of chronic duodenal ulcer with a climbing curve but no marked delay in emptying.

CHART 21 A.



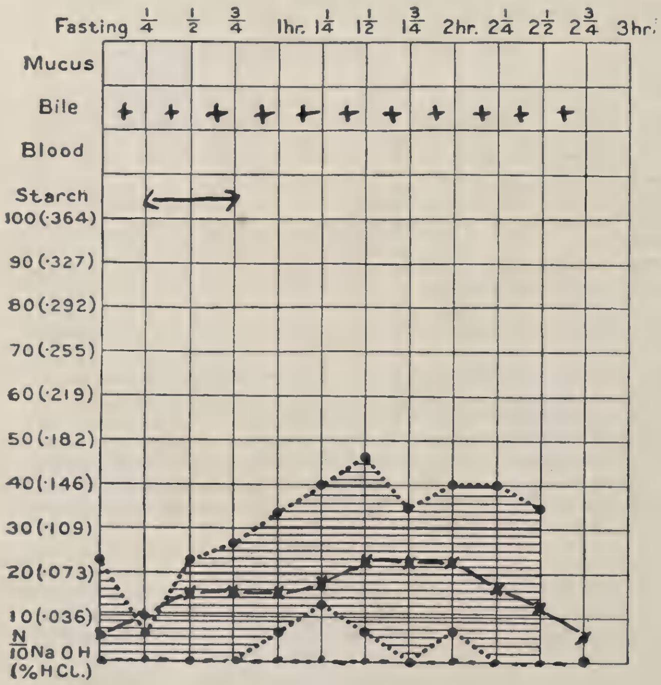
Pyloric stenosis with dilated stomach.

CHART 22 A.



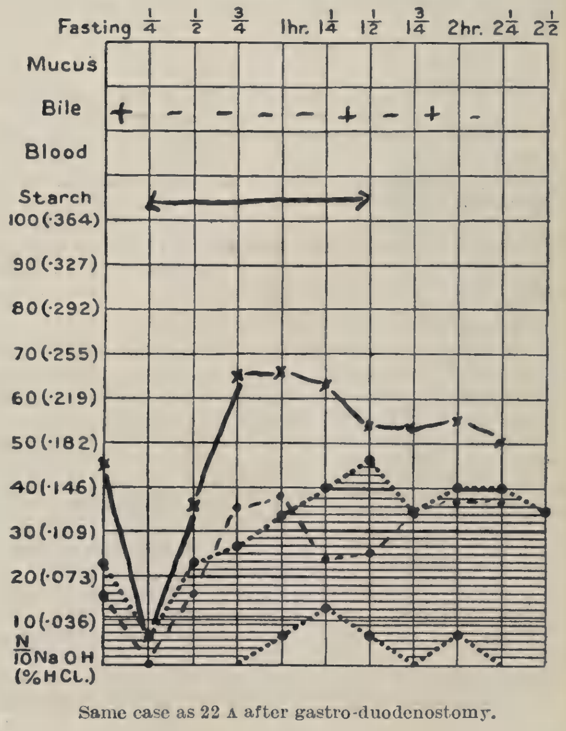
Duodenal ulcer with well-marked hypertonus.

CHART 21 B.



Same case as 21 A after operation.

CHART 22 B.



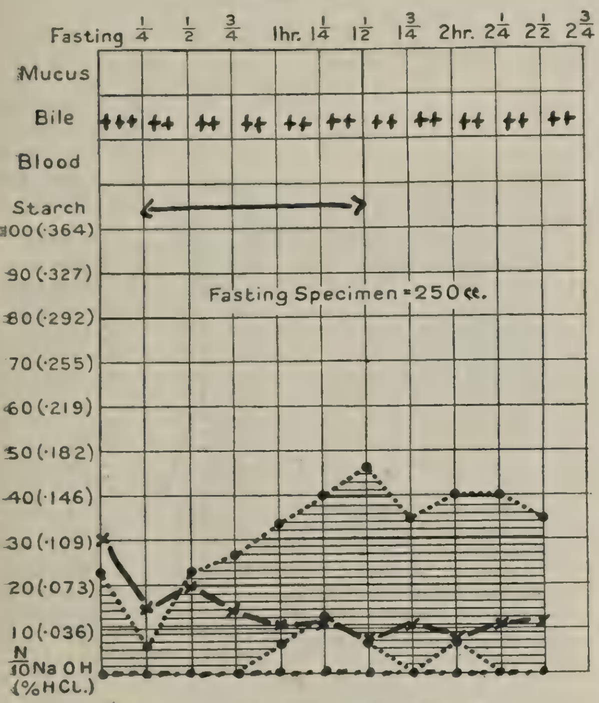
Same case as 22 A after gastro-duodenostomy.

Gastro-jejunostomy was performed with relief of symptoms. It will be noticed that the rate of emptying is reduced by half and that there is free bile regurgitation, indicating an efficient stoma. Although there is still hyperchlorhydria at one hour, the acid of the fasting secretion has fallen within normal limits and the duration of the hyperchlorhydria is reduced.

Charts 21 A and B are from a case of pyloric stenosis with gastric dilatation. The presence of bile at frequent intervals before operation, and in spite of the stenosis, suggests that gastric tonus must be low. The operation was completely successful both in draining the stomach and in securing neutralisation of acidity. Subjective symptoms were also relieved.

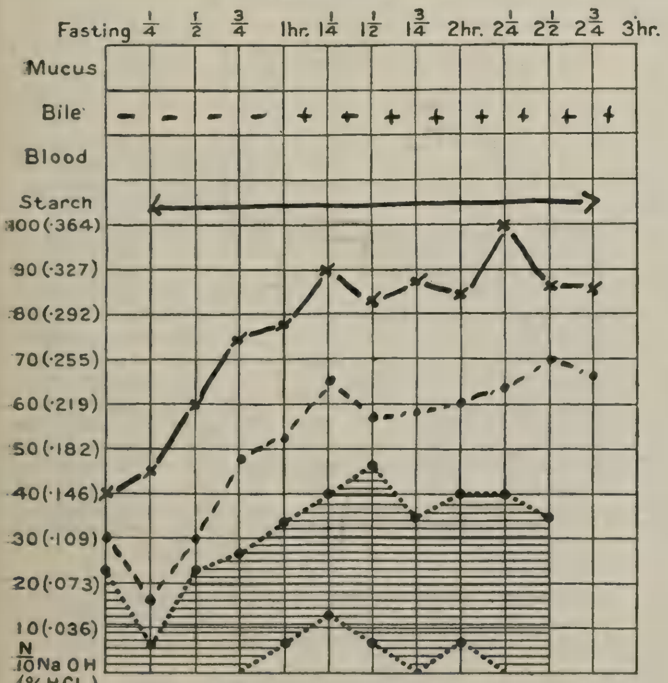
Charts 22 A and B are from a case of chronic duodenal ulcer adherent to the pancreas. There was well-marked hypertonus. After gastro-duodenostomy the acidity fell within normal limits and symptoms were at first relieved, but there was a recurrence of ulcer symptoms within two years.

CHART 23.



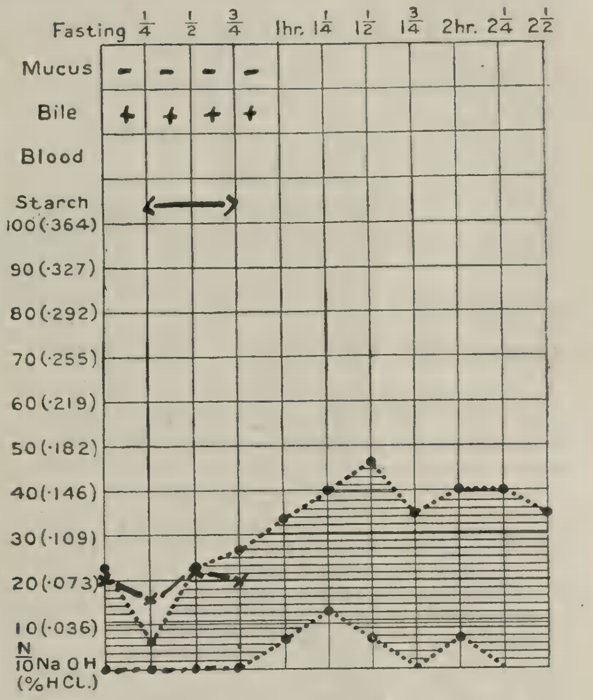
Gastro-jejunostomy. "Vicious circle" vomiting.

CHART 24.



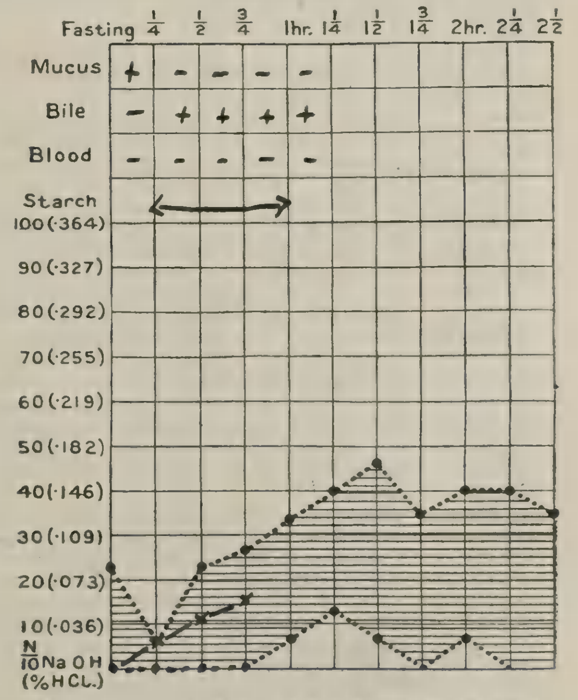
Gastro-jejunostomy. Stenosis of duodenum and stoma.

CHART 25.



Gastro-jejunostomy for gastric ulcer. Badly placed stoma. Persistence of ulcer in spite of neutralisation of acidity.

CHART 26.



Unnecessary gastro-jejunostomy. Too efficient stoma. Diarrhœa.

Chart 23 is from a case of gastro-enterostomy performed for an ulcer near the pylorus some years previously. In this case a diagnosis of "vicious circle" was evident on the history of profuse bilious vomiting. In spite of the normal emptying-rate there were 250 c.cm. of bile-stained fluid in the fasting specimen. At operation the diagnosis was shown to be correct and the jejunum was found to be flattened against the stomach.

Chart 24 is from a case of gastro-jejunostomy for duodenal ulcer followed by recurrence of ulcer symptoms. The only possible conclusion to be drawn from the curve is that stenosis both of the pylorus and the stoma is present, for it is a typical curve of simple pyloric stenosis. Bile found its way into the stomach in the latter half of the meal only. The diagnosis was confirmed at operation.

Chart 25 is from a case of lesser curvature ulcer persisting after gastro-jejunostomy. The very rapid emptying and the complete achlorhydria have not facilitated healing, and a radiogram showed that the anastomosis was made so far to the pyloric side of the ulcer and its incisura that no adequate reduction of tension in the fundic portion was achieved. The case is one of many which suggest that the presence of acid is not an essential factor for determining the perpetuation of an ulcer.

Chart 26 is from a case of gastro-jejunostomy with a too effectual stoma performed for reasons unknown. There was nothing in the history to suggest ulcer. The result was excessively rapid emptying causing diarrhœa and malnutrition with deficient gastric and pancreatic digestion. X ray examination showed complete evacuation of the heavy barium meal in ten minutes. The patient had on one occasion noticed fragments of hard-boiled egg in the stools within half an hour of eating it. The stools contained soaps, fatty acids, and meat fibres in excess of normal.

In my first lecture I showed that we have in the fractional test-meal a useful standard of motility or emptying-rate. In the present lecture I have indicated that of all the functions of the stomach requiring instrumental study the motility or emptying-rate is the most important. By a correlation of emptying-rate with the curve of acidity we can obtain an insight into the functional efficiency of the pylorus and the general muscular efficiency of the stomach which may greatly aid us in our clinical decisions and save us from therapeutic errors.

RECAPITULATION.

By way of recapitulation, I should like to direct attention once more to certain of the conceptions which I have attempted to define in the course of this review. Firstly, there are two main types of dyspeptic reaction—the *immediate* and the *delayed* (or those associated with a recently filled or an emptying stomach). Secondly, the causal or provocative factors are of two main types, the *pressor* and the *depressor*. Thirdly, the dyspeptic reactions are determined in part by these causal factors, but in part also by the physiological type or gastric habitus of the individual, and the gastric habitus again (when variant from the normal) is of two main types, the *hypersthenic* and the *hyposthenic*.

Immediate pain or discomfort is the common response with the hyposthenic habitus and in dyspepsias resulting from depressor influences. It is thus encountered more frequently in the female sex and in association with general debilitating diseases. It may also be encountered in the irritative dyspepsias if these develop in a patient with the hyposthenic habitus or with general debility; under such circumstances the syndrome of gastric ulcer may be reproduced.

Delayed pain or discomfort is the common response with the hypersthenic habitus or in dyspepsias resulting from pressor influences. It is thus encountered more frequently in the male sex and in association with central or reflex irritative causes. If any of these causes are present in association with the hypersthenic habitus the symptoms of duodenal ulcer may be reproduced. The more circumscribed the focus of irritation and the more nearly it is situated to the stomach the more sharply defined do the symptoms become, but even in a "worry" or "fatigue" dyspepsia we can sometimes detect the characters of the ulcer syndrome. If an irritative focus is developed in association with the normal habitus, which is present in from 70 to 80 per cent. of the population, the liability to dyspeptic symptoms is less than in the extreme physiological types and local symptoms are more in evidence.

Finally, whether we are concerned with clinical symptoms such as pain or nausea, or with radiological or chemical symptoms such as hypertonus, hypotonus, hyperchlorhydria, or hypochlorhydria, it is important to appreciate that each response expresses merely an exaggeration or depression of a normal reflex. The dyspeptic reaction cannot of itself inform us as to the exact nature of the underlying disease any more than dyspnœa or tachycardia can inform us as to the exact physical condition of the heart or the causes disturbing its function. Nevertheless an estimate of the nature and degree of the functional derangement is essential both for diagnosis and prognosis, and may materially influence choice of treatment.

Throughout these lectures I have tried to strike a just balance between what may, pardonably perhaps, be termed the field-observations of the physician, working as a naturalist, and the more detailed observations of the physician seeking to apply to his work the methods of the scientist—observations which must always be complementary to one another. In studying the disturbances of gastric function we rely first and foremost on our old-established clinical methods of interrogation and physical examination; for the proper application of these and other methods an understanding of normal function is essential. In the second place, we may have recourse to the physical methods of the X ray department and the chemical methods of the laboratory: from neither of these departments, excepting in the case of extreme deviations from the normal, or for the express purpose of confirming or allaying a suspicion of local organic disease, can we expect a final opinion. Once again, therefore, it falls to the physician, this time in a judicial capacity, to balance the evidence which has been furnished and to frame the final conclusion. Although accuracy in diagnosis is often enhanced, judgment, which is the most difficult part of our art, is never immediately made easier by the introduction of new tests or by the elaboration or modification of old ones. For this reason it is important from time to time to attempt, in the interests of practical medicine, a broad review of the state of our information on subjects of this kind.

I must gratefully acknowledge the assistance which I have received from my colleagues and from the references to the literature which have been necessary. I am, however, very conscious of the deficiencies of this survey, and can only claim that I have endeavoured to present as comprehensive a view of the subject as the time at my disposal would permit. If my remarks have been successful in emphasising the importance of symptoms and the need for further clinical research into the nature of symptoms, they will not have been altogether in vain. Always more attracted by the broad field of clinical study, I have made a few small excursions into the domain of physiology and morbid physiology, hoping to gain thereby some of the advantages which come from an altered point of view. I have not been disappointed. Nevertheless, as experience grows, and with it the opportunity of testing the practical value, the corrective influence, and also the limitations of the accessory diagnostic methods, the greater becomes my interest and belief in the older methods of observation, which no laboratory can teach, but which the contributions of my predecessors in this post and the tradition of our ancient College have done so much to foster.

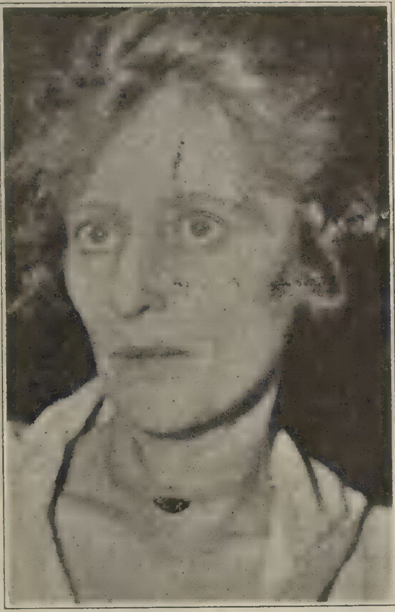
IODINE AS AN AID TO SURGERY IN THE TREATMENT OF EXOPHTHALMIC GOITRE.

BY ARNOLD S. JACKSON, M.D.,
M.S. IN SURGERY, MAYO FOUNDATION, MADISON, WISCONSIN.

SIXTY-THREE out of 66 patients with exophthalmic goitre, operated on at the Jackson Clinic between October, 1922, and October, 1924, were treated with iodine. In this series of cases there have been no surgical mortalities, neither have there been any medical deaths. No patient has been refused operation, and thyroidectomy or ligation has been performed with considerable risk in several instances.

The successful treatment of this group of patients may be attributed to the use of iodine. The introduction of iodine in the treatment of exophthalmic goitre is due to Plummer in March, 1922. Not only did this revolutionise our ideas concerning the effect of iodine in this disease, but it provided a means of successfully combating the dreaded clinical post-operative hyperthyroidism. It is almost two years since I have encountered this latter condition, whereas it was formerly considered a frequent and often fatal complication.

FIG. 1.



Case 33871. Advanced case of exophthalmic goitre five days following thyroidectomy. Patient had been bedridden for six months previous to admission. Ten days after treatment with iodine a test ligation was done. Three days later a thyroidectomy was performed with only slight reaction.

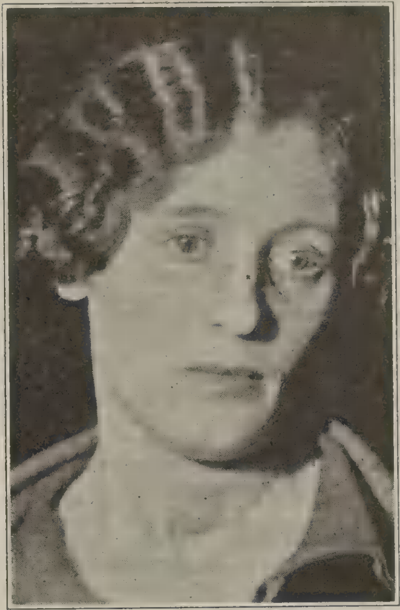
In this series of cases all but four received iodine pre-operatively. At first it was necessary to proceed with considerable caution and to experiment on each patient in the endeavour to ascertain the correct amount of iodine to be administered. Plummer first determined the optional dose to be ten drops of Lugol's solution (liquor iodi compositus) well diluted with water. Three of the patients in my series were given this dosage during a period of three months or longer (one case, six months) in order to discover the ultimate effect of iodine in cases of exophthalmic goitre. Although marked improvement was noted in each case, there was no indication at any time of a clinical cure; a low-grade hyperthyroidism persisted at all times with a basal metabolic rate averaging about plus 20 per cent. This is what might have been expected, as it is probable that iodine merely puts the thyroid gland at rest temporarily and allows it to complete its normal secretion.

During my early experience in thyroid surgery one or more ligations, or a multiple-stage thyroidectomy, was performed at the least indication. As we gained further knowledge of the remarkably beneficial effect of iodine the number of preliminary operations was reduced, so that the last 25 thyroidectomies have been performed without any previous operations. I would not hesitate to ligate now, however, if in doubt, and I urge others to proceed with similar caution.

Method of Administration of Iodine.

In carrying on investigations with iodine in various cases, I soon found that the degree of reaction following operation could be lessened by the following method: the dosage of Lugol's solution was gradually increased to 30 drops a day for all cases until 48 hours before operation, when 40 or even 50 drops were often given. Likewise, the period of pre-operative preparation was reduced to five days or less in the majority of cases. Patients have frequently been allowed to take the Lugol's solution at home and submit to operation on the morning after entering the hospital. The reaction was also reduced by the administration of Lugol's solution by proctoclysis as well as by the mouth, while the patient was convalescing after operation. Patients were all able to take nourishment on the day following operation; they were up and about on the fourth day, and usually left the hospital one or two days later. This régime did not include patients with badly decompensated hearts and visceral degeneration, nor the extreme cases of hyperthyroidism occasionally encountered. Patients who are seen for the first time in a crisis respond almost immediately to treatment with iodine, and there is cessation of vomiting and diarrhœa within 48 hours. These patients necessarily require more care, and a longer period of preparation.

FIG. 2.



Same patient three months after thyroidectomy. Weight had increased from 65 lb. on admission to 155 lb. Under iodine the metabolic rate dropped from plus 75 per cent. to plus 56 per cent. Three weeks after operation the rate was plus 7 per cent.

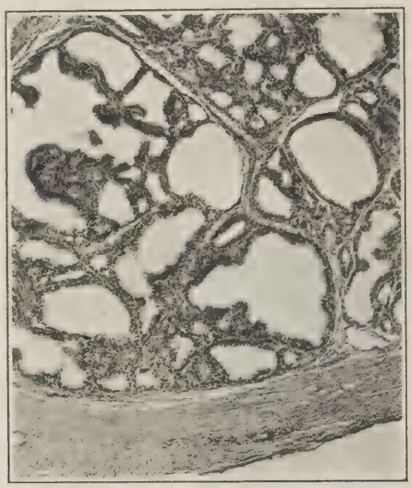
Clinical Improvement After Administration.

The clinical improvement following the administration of Lugol's solution usually becomes evident on the second or third day. First of all there is a cessation of the numerous purposeless movements of the extremities. Patients no longer thrash about in bed and chafe their arms and legs. The frightened, anxious, staring expression gives way to one of calm and composure. Exophthalmos persists, likewise the thrill and bruit, but in some cases there is a certain lessening of these clinical signs. Insomnia gives way to quiet restful sleep. With reduction in the rate of metabolism, the body tissues are no longer oxidised at such an extremely rapid rate and there is a marked gain in weight. The pulse-rate is noticeably slower and patients are no longer kept awake by a throbbing aorta or disturbed by the pulsations of the carotids.

Bedridden patients are able to walk about after a few days, so speedily do they gain in strength.

In proportion to the degree of clinical improvement there was a reduction in the basal metabolic rate, which averaged plus 19 per cent. in this series. In every case in which the administration of Lugol's solution was continued through necessity or choice for more than the average preparatory period, there was a still further reduction in the rate. As I knew that patients could not be clinically cured by the use of iodine, and as I was confident that they would undergo thyroidectomy safely, I have felt there was no indication for prolonging the period of preparation merely to gain a temporary improvement beyond the point where the patient could be considered a good operative risk.

FIG. 3.

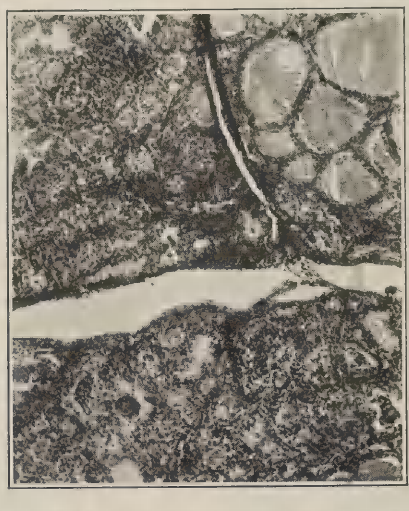


Typical exophthalmic goitre: no pre-operative treatment with iodine had been given. Note the characteristic infolding of the epithelium and the large epithelial cells.

Factors Reducing Operative Mortality.

Undoubtedly factors other than iodine therapy are important in the great reduction in operative mortality in exophthalmic goitre. Of these, I believe the following are paramount. The development of operating teams whose work is so coördinated that the element of time is no longer of importance in considering the risk of operation. The surgeon who persists in performing the many trivial details of every operation cannot hope to have his results compare favourably with those of the highly perfected teams developed by the Mayos and Crile. Next in importance is the fact that patients are now seen by the surgeon in the early stages of the disease before marked visceral changes have occurred. This is due to a widespread dissemination of knowledge pertaining to the symptoms of exophthalmic goitre. The people will soon class the physician who fails to diagnose this condition until a crisis has occurred with the one who remains oblivious to the symptoms of appendicitis until the appendix has ruptured. Brilliant diagnoses of early cases of toxic goitre are now frequently being made by the family physician.

FIG. 5.

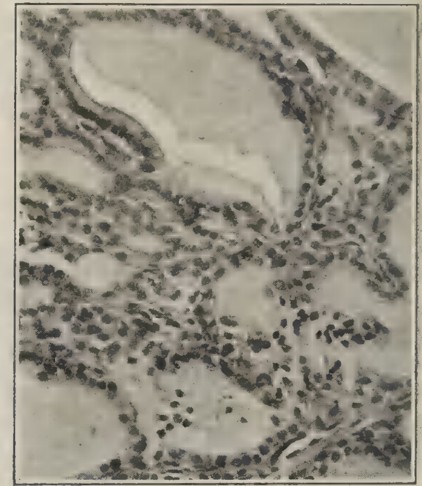


Case 34617. This patient had a low-grade hyperthyroidism, the basal metabolic rate running between plus 20 per cent. and plus 35 per cent. Although she was kept on iodine for six months, the symptoms of hyperthyroidism persisted and the rate never dropped below plus 18 per cent. The pathological picture shows a marked tendency for colloid to replace hyperplasia.

Choice of Anæsthetic.

Finally, the improved methods of local and general anæsthesia have been of inestimable value in lowering operative mortality. In my group of cases 95 per cent. of the patients were given the morphine scopolamine local anæsthesia. Other clinics report equally good results with other forms of anæsthesia. The fact that in this series of cases there was not a single instance of post-operative pneumonia, injury to the vocal cord, post-operative hæmorrhage, or, in fact, any complication, argues favourably for this method of anæsthesia. Considerable tact and skill are required in handling patients with goitre, and the successful outcome of the case may be considerably influenced by the nurses and physicians in direct charge of the patient. We have not found it necessary to operate while the patient is in bed, neither have we kept the patient uninformed of the date of operation. When patients are given an opportunity to converse with those who have had successful operations, the fear and hysteria are generally promptly dissipated.

FIG. 4.



Case 42475. The pathological appearance of the gland in a case of exophthalmic goitre following pre-operative treatment with iodine. The gland tending to assume a normal apearance, colloid replacing areas of hyperplasia. In certain sections, however, well-defined areas of hyperplasia still appear.

End-Results.

Sufficient time has not elapsed since the institution of treatment to consider the end-results in this group of patients, but a survey of their present condition may give some clue to the ultimate prognosis. Only 25 of the 68 patients at the time of admission were carrying on their full occupations: 15 were partially incapacitated and 28 were either bedridden or totally incapable of performing their routine duties. Fifty-two of the patients are now performing their regular duties, but are observing general post-operative instructions, including frequent periods of relaxation and rest. The remaining 16 are capable of performing full work, but are now being restrained until they have had a longer post-operative rest period. With many of these people it is a question of finance; one woman, for example, finds it necessary to cap 18,000 battery cartons every day in order to support herself. The fact that none of these patients were hospitalised an average of more than five days is an answer to those who would advocate measures other than surgery because of the long period of restraint from work. Moreover, these patients are not partially cured and still running an intermittent or low-grade hyperthyroidism with its resultant damage to the cardio-vascular-renal system. They are restored to health, with a normal metabolism. The average gain in weight three months after the operation has been 15 lb., and at the end of six months 26 lb. Two patients have gained more than 70 lb., and many have gained 40 or 50 lb. since operation.

Effect on Basal Metabolism.

The average basal metabolic rate on admission was plus 49 per cent. After preliminary rest and treatment with Lugol's solution this rate dropped to plus 30 per cent., and three weeks following thyroidectomy the rate was plus 8 per cent. Two patients have developed recurrences; both were operated on at a time when the factor of post-operative hyperthyroidism was still a dreaded possibility. One patient received no Lugol's solution; the other had only a small amount. In both cases it was necessary to operate as soon as possible, and operation was technically difficult because of the vascular, friable nature of the gland due to increased collateral circulation following ligations. In the haste to complete the operation without too long delay sufficient gland was not removed. Now, I frequently remove four-fifths of every gland. A second operation has been performed on one of these patients, and to date he has gained 55 lb. The other patient is temporarily under control with Lugol's solution.

In a previous article attention was called to the fact that iodine causes a marked change in the pathological picture of the gland, colloid tending to replace areas of hyperplasia and the gland tending to assume a normal appearance.

Summary.

The use of iodine, as advocated by Plummer in the treatment of exophthalmic goitre, is the most important factor in reducing the operative mortality in this series.

The development of a highly perfected operation, with the consequent reduction in time, the fact that patients come to operation at an early stage in the disease, and improved methods of anæsthesia, are other factors tending to reduce the operative mortality.

Iodine will not permanently cure, but merely temporarily alleviate the symptoms of exophthalmic goitre.

The use of iodine will prevent or terminate a fatal crisis as well as post-operative hyperthyroidism.

The necessity for ligation is eliminated in 90 per cent. of cases by the use of iodine.

Patients are given 30 drops of Lugol's solution daily for three days and 40 or 50 drops for one or two days. Following operation Lugol's solution is administered by mouth and by proctoclysis.

The average stay in the hospital is reduced to five days, as the patients are able to take the pre-operative treatment at home.

Within 48 hours after the ingestion of iodine there is a marked abatement of all the symptoms of hyperthyroidism. The nervous, vascular, and digestive systems are all favourably influenced.

There is an average reduction of plus 19 per cent. in the basal metabolic rate.

SOME TOXIC CONDITIONS FOLLOWING ETHER ANÆSTHESIA

AND THEIR SUCCESSFUL TREATMENT.*

BY R. J. MINNITT, M.B., CH.B. LIVERP.,
SENIOR HON. ANÆSTHETIST, ROYAL LIVERPOOL CHILDREN'S HOSPITAL; HONORARY ANÆSTHETIST, ROYAL INFIRMARY, DAVID LEWIS NORTHERN HOSPITAL, AND HOSPITAL FOR WOMEN, LIVERPOOL.

IN THE LANCET of Sept. 27th, 1924, Pemberton and Cunningham showed that ether anæsthesia produced a hyperglycæmia, not only in the diabetic, but also in the normal individual, and they there stated that in the diabetic case the risks run were due to anæsthesia and shock, both of which produced the hyperglycæmia. From the following account of five selected cases in an investigation undertaken by me I shall try and show: That to a lesser extent the same is true in the non-diabetic; that there is a definite relationship between this hyperglycæmia, associated with ether anæsthesia, and the toxic symptoms which follow; also, that the treatment prescribed for their amelioration should be on the lines which have been found so successful in the case of the diabetic. These toxic symptoms can be briefly described as vomiting, pallor, or shock, and acidosis or ketonuria.

Case Records.

CASE 1. *Resection of the Stomach.*—The blood-sugar was estimated before the administration of the anæsthetic, and each half hour until its completion. The amount of ether used is shown during each interval. In this case there were no post-anæsthetic toxic symptoms, and the graph (Fig. 1) shows that there is a definite rise in blood-sugar, varying with the length of administration of the anæsthetic, but no further secondary rise, the conclusion drawn being that where the blood-sugar falls after the anæsthetic to a more or less normal level, and does not rise again, the patient suffers little, if anything, from toxic symptoms, such as vomiting, pallor, or acidosis.

---

* Condensed from a paper read before the Liverpool Medical Institution.

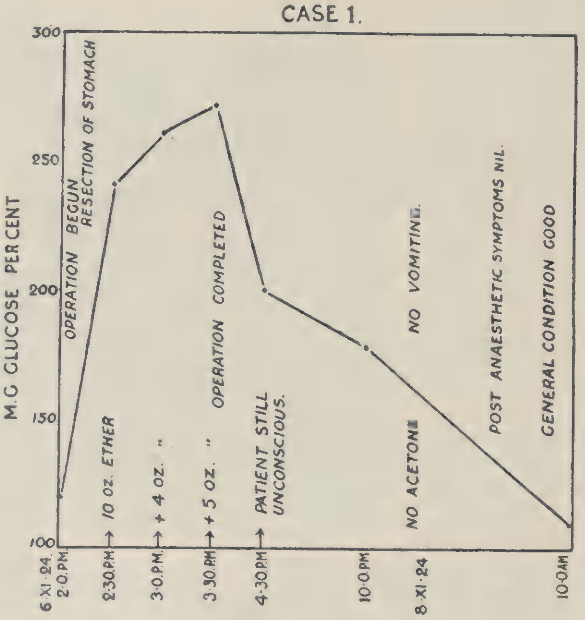

FIG. 1.

CASE 2 shows the sugar-tolerance test carried out before and after the anæsthetic in an operation for *double inguinal hernia*. The left-hand part of the graph (Fig. 2) portrays the blood-sugar curve after giving 50 g. of glucose by the mouth the day before the operation. The dotted lines in the centre of the graph show the effect upon the blood-sugar of the anæsthetic, and the right-hand part of the graph the rise in blood-sugar after the administration of 50 g. of glucose the day following the operation. The conclusion drawn from these tests is that the anæsthetic appears in some way to impair the efficiency of the pancreas in dealing with sugar.

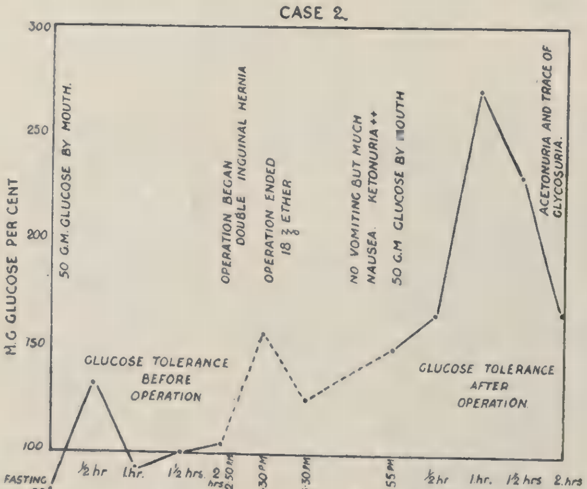

FIG. 2.

CASE 3. *Gastro-enterostomy*.—The rise in blood-sugar and its fall during and after the anæsthetic is shown (Fig. 3), with a secondary rise the following day, accompanied by toxic symptoms, such as vomiting, pallor, and acidosis. Upon the administration of insulin there is seen the fall in blood-sugar, and the simultaneous improvement in the condition of the patient.

CASE 4. *Ectopic Gestation and Appendix.*—The post-anæsthetic toxic symptoms were very severe, and the patient was unsuccessfully treated with alkalies. The graph (Fig. 4) shows how the blood-sugar did not fall in amount until after the third dose of insulin, when the condition of the patient became better. This suggests that the administration of insulin may have to be prolonged until the blood-sugar is reduced, for it is not until then that improvement takes place.

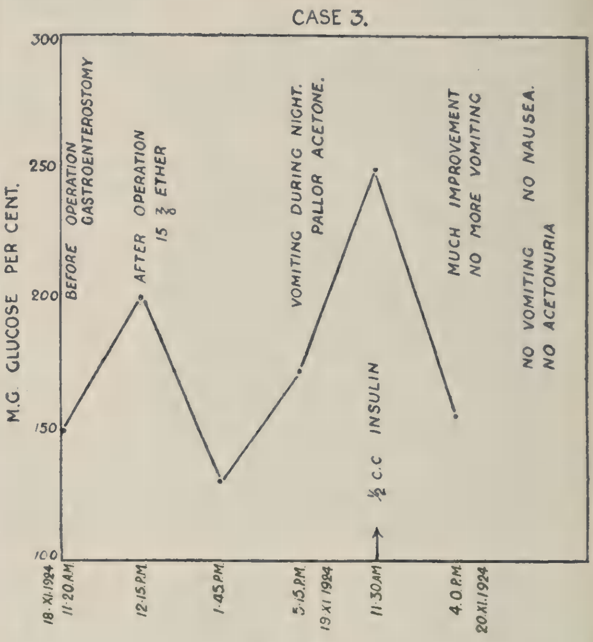

FIG. 3.

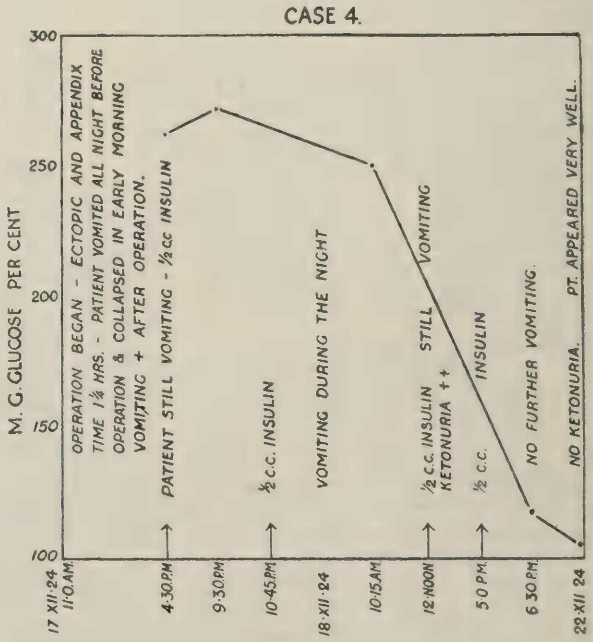

FIG. 4.

CASE 5.—*Double hernia* shows the effect of the administration of insulin and glucose given immediately upon the conclusion of the anæsthetic, there being no secondary rise of blood-sugar nor development of toxic symptoms. (Fig. 5.) Hence insulin can prevent or mitigate toxic symptoms before they arise.

In the *Journal of the American Medical Association* of August 4th, 1923, Thalhimer, of Milwaukee, reported the treatment of three cases of post-operative non-diabetic acidosis by means of insulin. In one case there was no improvement with gastric lavage and glucose, but three hours after the hypodermic injection of insulin vomiting ceased. In another case two doses of insulin were required before improvement took place. In the third case, that of a child of 5, too small a dose of insulin was given to alter the acidosis or prevent the blood-sugar from rising. Twice as much was given the following morning, which had a definite effect upon the blood-sugar, and vomiting ceased.

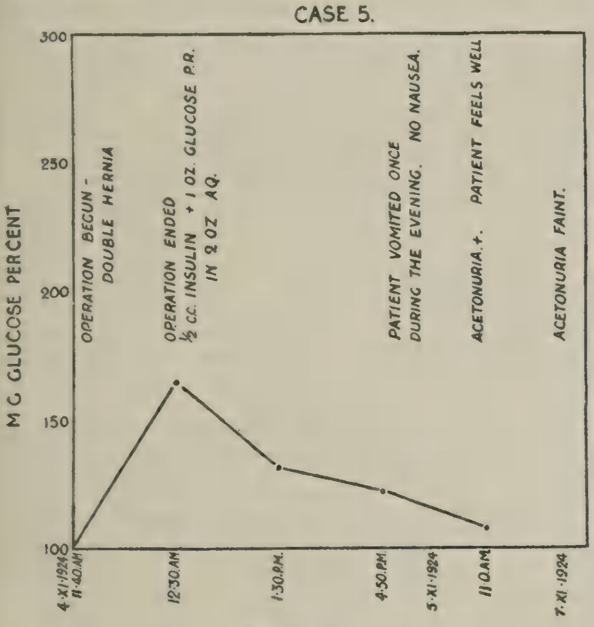

FIG. 5.

In the same journal of Dec. 13th, 1924, appeared an article describing the treatment of three cases of shock after operation, with glucose and insulin, but there is no mention of any blood-sugar estimations having been made.

From the account of these cases I am surprised at the large doses of insulin used, and it also occurs to me that it is very difficult to differentiate between the toxic effects of the anæsthetic upon certain patients, and the result of shock. One thing, however, seems certain, that we have in insulin a remedy for the toxic symptoms following ether anæsthesia, and that in some mysterious way, not yet fully elucidated, these conditions are associated with something which affects blood-sugar.

SUSSEX PROVIDENT SCHEME.—The annual meeting in connexion with the Sussex Provident Scheme was held at Brighton on March 21st. Very encouraging figures were presented. In January, 1924, it was shown there were 93 groups with 6699 subscribers and 10,592 dependents, whereas in January this year there were 187 groups with 10,456 subscribers and 16,044 dependents, a total of 26,500 people entitled to the benefits of the scheme; 620 subscribers and their dependents had received in-patient treatment for a period of 13,723 days at a cost of £4562 5*s.* 3*d.*, and 1893 people had made 10,744 attendances for the various specialised forms of out-patient treatment at a cost of £957 19*s.* 3*d.* An abnormal amount of sickness was experienced during the year and, in consequence, it had only been possible to pay 90 per cent. of the claims of the hospitals instead of the full amount as had been done hitherto. The whole of the administrative expenses amounted to only £423 12*s.* 3*d.* Details of the allocation of £5500 to the local hospitals for services rendered to subscribers during 1924 were given in THE LANCET of Feb. 14th.

DIFFICULTIES IN THE DIAGNOSIS OF THE ACUTE PHASE OF EPIDEMIC ENCEPHALITIS IN CHILDREN.

BY JAMES L. HALLIDAY, M.B. GLASG.,
D.P.H. EDIN. & GLASG.,
LATE ASSISTANT PHYSICIAN, CITY OF GLASGOW FEVER HOSPITAL, RUCHILL.

THE experience presented here was obtained in a fever hospital where encephalitis was only one infectious disease among others. The later manifestations of encephalitis are usually sufficiently striking to make the diagnosis fairly sure, but during its very early stages the symptoms are sometimes merely those peculiar to acute fevers in general. It is at the onset that difficulties in diagnosis are met with on a large scale. The first part of this paper deals with the diseases which in practice were found to simulate encephalitis; the second part draws attention to certain symptoms through a misunderstanding of which errors arose.

DISEASES WHICH SIMULATE ENCEPHALITIS.

Between the months of March and July, 1924, encephalitis was epidemic in Glasgow: 81 children (ages 0–16) certified encephalitis were admitted to Ruchill Fever Hospital, and of that number 40—that is, 47·5 per cent.—were considered to be definite cases. There was, therefore, a diagnostic error of 52·5 per cent. The diagnostic error for 121 adults certified encephalitis during the same period was 30·2 per cent. Encephalitis, therefore, is more difficult to diagnose in children than in adults. On examination four months after the onset, 37 of the 40 cases considered to be encephalitis were found to be suffering from sequelæ characteristic of the disease; none of the cases where the diagnosis was altered showed any of the later traits of encephalitis. The apportioning of the figures may, therefore, be taken as approximately accurate.

The 41 cases in which the diagnosis was altered were grouped thus:—

Gastro-enteritis with toxæmia	14
Tuberculous meningitis	13
Pneumonia	8
Rheumatic group	2
Septic sores	1
No appreciable disease	2
Early tuberculous peritonitis	1

The diseases most often confused with encephalitis in children were, therefore, gastro-enteritis, tuberculous meningitis, and pneumonia. Tuberculous meningitis is well recognised to be a stumbling block, but so far stress has not been laid on the other two conditions as being liable to mislead.

Gastro-Enteritis with Toxæmia.

Two of these cases were infants under one year. Both were in a marasmic state and were "lethargic." They were admitted with a history of squint, which on investigation was found to be due to incoördination of the eye-muscles aggravated by their weak condition. The remainder had a history, previous to admission, of vomiting, with or without diarrhœa, which was associated with delirium or drowsiness, and accompanied by an elevated temperature. Some had suffered from similar attacks on previous occasions, and these might be labelled cases of cyclical vomiting. The milder cases showed no symptoms while in hospital, except perhaps a slight drowsiness and a small elevation of temperature which quickly subsided. The more severe cases (four in number) presented symptoms, many of which are seen in encephalitis, and the following case may be quoted as an illustration of a severe toxæmia of gastro-intestinal origin:—

J. M. G., a boy aged 10 years, certified encephalitis, was admitted to hospital on his second day of illness. The previous morning he complained of intense frontal headache and severe abdominal pain. In the afternoon he had become drowsy and at night he was delirious, attempting to get out of bed. On admission he looked acutely ill. His lips were cyanosed and he sweated profusely; his pulse was of poor quality, and he lay in a restless delirium. His tongue was thickly coated and his mouth dirty. From time to time he vomited a greenish vomit and his breath was heavy with the smell of acetone. The stools were loose, green, and contained mucus. His temperature was high—viz., 102·5° F. For several days his temperature remained elevated and he remained in a similar condition, drowsiness alternating with the bouts of delirium. On being roused he was extremely irritable and mentally confused. His eyelids were drooping and suggested a double ptosis. He occasionally had sighing respirations. When the temperature fell he quickly improved and he was perfectly bright and normal in a week. During his illness the urine gave a strongly positive Rothera reaction. (Gerhardt's reaction was also positive.) The ketone bodies did not disappear from his urine till his fifteenth day in hospital. Lumbar puncture was done on his third day of illness after taking a series of specimens for blood-sugar estimation. The spinal fluid gave a faintly positive Rothera reaction, otherwise it showed nothing abnormal. The blood-sugar curve rose in one hour from 0·11 per cent. to 0·253 per cent., and did not regain its original level after three hours. On inquiry into his previous history it was found that he was subject to bilious attacks. Three months after dismissal he reported himself to the hospital. During the interval he had apparently been quite well.

When recorded on paper the fact that the trouble was *not* encephalitis seems obvious, but in practice the matter was not so simple. The association of delirium, sighing respirations, drowsiness, and temperature is common to both conditions. The drooping of the eyelids suggested a true ptosis, and during the epidemic encephalitis in children frequently began with vomiting and occasionally with diarrhœa. On clinical grounds the diagnosis was made on the prominence of the gastro-intestinal symptoms and the obtrusive odour of acetone in the breath, which was confirmed by the positive Rothera reaction given by the urine

Tuberculous Meningitis.

The nature of the disease is usually evident from clinical evidence alone, but confirmation, and in some cases, especially during an epidemic of encephalitis, the diagnosis depends on the examination of the spinal fluid. A diagnosis of tuberculous meningitis was made from the following findings in the spinal fluid :—

1. *Those Peculiar to Tuberculous Meningitis.*

(*a*) *Pellicle Formation.*—In tuberculous meningitis after standing from one-half to 12 hours the fluid usually clotted. There was no clot in encephalitis. [In the journals of the hospital is found the record of what was presumably a case of the meningeal type in which pellicle formation occurred. The post-mortem findings were those of encephalitis—namely, sleeve hæmorrhages, round cells, perivascular infiltration, and degenerated nerve cells. The meninges were infiltrated with mononuclears and plasma cells. No organisms were found.]

(*b*) *Differential Cell Count.*—Mononuclears were the predominating cells in the fluid from tuberculous meningitis, but polymorphs were usually also found even up to 60 per cent. The cells in encephalitis were mononuclears only and polymorphs did not occur.

(*c*) *Sugar Content.*—The sugar content of the fluid was reduced in tuberculous meningitis. The only accurate method of determining the lowest point is by quantitative means. Thus, the sugar content of fluids from seven cases of tuberculous meningitis varied from 0·019 per cent. to 0·036 per cent., as estimated by MacLean's method, whereas in a series of fluids from eight normal persons the sugar content varied from 0·050 per cent. to 0·065 per cent. The following rapid method for determining a diminished sugar content was evolved and found useful. On boiling together for two minutes exactly equal parts of Fehling's solution and the spinal fluid from a healthy subject or a case of encephalitis, and on examining immediately against a dark background, a red or brown opalescence is found. When fluid from tuberculous meningitis is employed there results either a green opalescence or else no reduction takes place. In all instances by transmitted light the boiled solution should remain blue.

(*d*) *Tubercle Bacillus in the Pellicle.*—The bacillus was found in 80 per cent. of cases.

2. *Those Common to Encephalitis and to Tuberculous Meningitis.*

(*a*) *A Clear Fluid Under Increased Pressure.*—The pressure in encephalitis was not usually so marked as in meningitis.

(*b*) *An Increased Cell Count.*—The count was usually higher in meningitis, but in several instances in children counts over 300 per c.cm. were obtained in encephalitis.

(*c*) *Increase of Globulin.*—The Nonne-Apelt reaction (Phase I.) was employed. This test must be performed immediately after the withdrawal of the fluid. If pellicle formation occurs the precipitation may be diminished, or even absent. This test was usually only faintly positive in the cases of encephalitis where it occurred (18 per cent.).

The findings showed great variation. Thus, in tuberculous meningitis clot did not always form; tubercle bacilli were not always found; mononuclears sometimes occurred alone, polymorphs being absent, and the sugar content of the fluid might be but little below normal. In encephalitis the fluid may be blood-stained, though this did not happen in the series in question; the pressure was not invariably increased, the cell-count was often within normal limits—i.e., under 5 per c.cm.—and globulin increase was inconstant. Lange's colloidal gold reaction gave a meningitic type of curve in cases of tuberculous meningitis. In encephalitis a luetic type of curve often occurred, but as a similar curve was found in several of the severer cases of gastro-enteritis with ketonuria (perhaps through alteration in the hydrogen-ion concentration of the spinal fluid) the consideration of its place in the routine examination of the spinal fluid is omitted. The results of this test seem to be of constant value only in the hands of an expert.

The following example illustrates the difficulties met with in a case clinically resembling both diseases, and illustrates well the value of examining the spinal fluid :—

J. M., a boy aged 4 years, certified encephalitis lethargica, was admitted to hospital on the fifteenth day of illness. The illness began with vomiting and headache. He became drowsy and suffered from time to time from pain on the right side of his face. On admission he complained of pain in the back of his neck. His head was slightly retracted and the neck muscles were rigid. The pupils reacted well. The abdominal reflex was depressed. Kernig's sign was indefinite. Pulmonary signs were absent. His appearance and history suggested tuberculous meningitis. There was no tuberculosis in the family.

Lumbar puncture after six hours' starvation : Cell count, 210 per c.mm., 6 per cent. being polymorphs. Nonne-Apelt test : Slight milkiness. Sugar : Green opalescence against a dark background on boiling with Fehling's solution. By estimation : 0·035 per cent. No pellicle formed on standing for 24 hours and no tubercle bacilli were found after centrifuging.

In favour of meningitis were the presence of polymorphs and the low sugar content, but the reading for this, 0·035 per cent., was not far below 0·050 per cent., the lowest figure in the series of normal fluids. The absence of clot was unusual in meningitis. The cell-count and the globulin increase would conform with either disease.

Three days later the head retraction was much less evident. There was ptosis of the left eyelid. The pupils were dilated and fixed. Continuous myoclonic movements of the muscles of the fingers and forearms were present. Both cheeks showed occasional twitching. The child's condition was very serious. The temperature had been swinging from 98° to 102° F., the pulse-rate had varied between 60 and 140; the respirations had crept up from 30 to 45.

Lumbar puncture repeated after six hours' starvation : Fluid clear under considerably increased pressure. Cell count, 290 per c.mm., 2 per cent. being polymorphs. Nonne-Apelt test : Definite milkiness. Sugar estimation : 0·024 per cent. Again no clot formed and no tubercle bacilli were found.

Two days later the child was obviously going to die. He was unconscious. The respirations were 60 and the pulse-rate and temperature still swinging. There was double ptosis; the left pupil remained dilated and fixed, the right being minutely contracted. The right arm and hand were rigid and held against the body in the position of tetany. The left arm made vague searching movements into the air.

There was abdominal retraction and retention of urine. Next day the boy died. At the post-mortem the gelatinous exudate at the base of the brain was found to be swarming with tubercle bacilli.

The variety of symptoms—viz., ocular palsies, myoclonic movements, rigidity, &c., though not uncommon in tuberculous meningitis, made the diagnosis doubtful from the clinical point of view, especially as encephalitis was rife at the time. The spinal fluid did not clot—a rare occurrence in tuberculous meningitis—and it happened that the bacilli were not found. The presence of polymorphs and the low sugar content alone made possible a sure diagnosis.

Pneumonia.

The source of confusion in these cases was the sudden onset accompanied by such symptoms as convulsions, twitchings, headache, drowsiness, delirium, meningism, vomiting, and pain in the side. These patients were usually admitted on the first or second day of illness when physical signs in the chest were indefinite. But the error in diagnosis may be the other way, as is seen in the following case of encephalitis which was certified pneumonia :—

M. D., a boy aged 9 years, previously in perfect health, was certified pneumonia and admitted to hospital with a history of severe pain in the left side, which began abruptly four days before. He had a spasmodic dry cough, but no spit. On examination the boy looked ill; his respirations were jerky and irregular, being on an average about 30 to the minute. His temperature was swinging between 98° and 100° F., and the pulse-rate varied from 88 to 120. No physical signs were found in the chest. Four days after admission generalised choreiform movements appeared, which were more marked at night. The pain had disappeared by that time, and he was perfectly intelligent. Examination of the spinal fluid proved negative. This restlessness continued for a month and was associated with attacks of lethargy during which the boy could not be properly roused. At the end of two months the choreiform movements had ceased; night restlessness persisted, and he was drowsy in the mornings. He was rapidly becoming thinner. A new movement then began to develop—viz., myoclonic twitchings causing abduction of the arm with internal rotation of the forearm. During his fourth month of illness he presented a typical picture. The flapping movements of the arms synchronised with his respirations, the rhythm of both being about 50 to the minute. He was known in the ward as "the penguin." With head hanging forward and chin resting on sternum he shuffled along panting and flapping. The movements did not cease during sleep. The arm movements and the respirations could be dissociated in rhythm for a short time; thus he could slow his respirations, bringing them down to about 25 per minute, while the movements of the arms maintained a rhythm of 50, but the rhythm of the arms could not be voluntarily altered.

SYMPTOMS COMMONLY MISINTERPRETED.

The onset of encephalitis was sometimes explosive, or a child might be vaguely unwell for days before the disease definitely declared itself. In the first instance the onset of the illness could be determined almost to a minute; in the second any reckoning of the time of onset was uncertain. The following table of the incidence of the commonest symptoms during the first and second days of illness must be read with these facts in mind :—

	Per cent.		Per cent.
Headache	51	Sleeplessness	21
Lethargy	45	Myoclonic and choreiform movements ..	21
Squint and diplopia ..	39	Neuralgic pains.. ..	18
Vomiting	33		
Delirium	24		

Headache, vomiting, delirium, and sleeplessness are early symptoms of many diseases. The myoclonic movements in tuberculous meningitis, the choreiform movements in the rheumatic group, and the pain in the side in pneumonia were sufficient in several cases to suggest encephalitis during the epidemic. Lethargy and diplopia are significant symptoms, but in several instances were misinterpreted.

Double Vision.

That half of the children, notified as encephalitis and admitted to hospital, did not suffer from the disease is due partly to the inherent difficulty in the diagnosis and partly to the fact that the epidemic was so well advertised. The public health authority were anxious that every mild or suspicious case should be certified and admitted to hospital for observation; medical practitioners were everywhere on the outlook for the disease, and newspapers published, almost daily, paragraphs informing the public of the fell significance of "drowsiness and seeing double." As the result of this publicity details of medical history previous to admission to hospital were often the result of suggestion. Thus it was not uncommon for a mother to bring up a baby a few months old and relate that it was "sleeping and seeing double"; or for a child to say that it was seeing double after the idea had been suggested by a parent. "Seeing double" was a phrase the significance of which had to be most carefully searched for. At times, especially in the gastro-enteritis and pneumonia groups, it connoted a polyopia due to delirium.

Lethargy.

It is difficult to decide where drowsiness ends and lethargy begins. Children when out of sorts from minor ailments are often drowsy. Children suffering from graver diseases, such as tuberculous meningitis and severe toxæmia, may be in a typically lethargic state. In the absence of other symptoms suggestive of encephalitis these factors were responsible for erroneous diagnosis during the epidemic.

Temperature.

The temperature chart was not found to be of much assistance in diagnosis, except in the case of pneumonia. Eight children with encephalitis were admitted to hospital before the fourth day of illness. During the first week of their residence in hospital two showed no temperature elevation, six had temperature showing irregular movements, four up to a maximum of 101° F. and two up to a maximum of 102°. Severe cases of intestinal toxæmia had irregular temperatures, which attained higher levels, but the milder cases did not exceed 99·5°. The charts in tuberculous meningitis showed great variation. Several did not rise above 100°, even immediately before death.

Ketonuria.

Of assistance in the diagnosis of intestinal toxæmia is the markedly positive Rothera reaction obtained in such cases, but ketonuria is common in childhood and was present in 80 per cent. of the children suffering from encephalitis during their first week in hospital, and in all cases of tuberculous meningitis up till death.

SUMMARY.

(1) In children the diseases most liable to be confused with early encephalitis are: Gastro-enteritis, tuberculous meningitis, and pneumonia.

(2) Examination of the cerebro-spinal fluid will always exclude meningitis, and in certain instances will establish a diagnosis of encephalitis.

(3) In gastro-enteritis the gastro-intestinal symptoms are often overlooked on account of others suggesting a disease of the nervous system, such as headache, delirium, drowsiness, sighing respirations, and pseudo-ptosis.

(4) Pneumonia in its early stages before the development of physical signs in the chest may be mistaken for encephalitis when it is ushered in by convulsions, twitchings, delirium, meningism, drowsiness, vomiting, and pain in the side. On the other hand, pain in the side, a cough, and rapid respirations may be the first symptoms of encephalitis.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

ENDOCRINE THERAPY.

(Continued from p. 740.)

AT the resumed meeting the chair was occupied by Dr. LANGDON BROWN.

Dr. H. CRICHTON-MILLER pointed out the importance of the endocrine gland secretions from the subjective aspect. There was much need of evidence as to their effect for functional sufferers especially. A drug house of high standing, which desired its name to be withheld, had placed at his disposal a series of tablets, for both men and women, for experimental purposes. They were labelled simply with the letters of the alphabet, and some members of the staff at his clinic, and other medical volunteers, would consume them and report results. Dr. Crichton-Miller expressed the hope that Prof. Swale Vincent would join the band of volunteers.

Mr. J. E. R. MCDONAGH spoke of the effects of those glandular extracts with which he had experimented on animals—i.e., adrenalin, thyroxin, insulin, and ageratin (testicular extract). His object in this research was to ascertain the effects of the drugs on the blood and organs and so to arrive at a basis for their chemo-therapeutic employment in man. Many of the extracts were derivatives of the amino acids. Though the amino was the most active group, the action of the compound really depended on the way in which this group was checked. Adrenalin caused the protein particles in the plasma to increase in number, and then to go into solution, and this dual action of conduction and dehydration caused constriction of capillaries and a consequent rise of blood pressure. The action of adrenalin, he said, was not specific. Insulin caused hydration of the protein particles, and adrenalin proved to be an antidote because it caused dispersion of the hydrated particles. When protein particles increased in size they were likely to be precipitated in capillaries, and if in the cerebral ones, fits and convulsions ending in coma ensued; while when this took place in the lungs there was the pulmonary form of shock. Adrenalin was not powerful enough in these conditions, and it should be substituted by glucose injected intravenously, and oxygen injected subcutaneously. Adrenalin was apt to fail as a styptic, because its later action of dehydration caused coagulation to be retarded. Thyroxin caused a slower dehydration of protein particles than did adrenalin, hence it was more valuable in chronic diseases; in the chronic stages of disease the protein particles increased in size and became too independent. In his view, malignancy was simply an expression of protein hydration. When the particles gradually increased in size, thyroxin could break them up. Its action could be enhanced by the simultaneous employment of colloid iodine. Insulin caused hydration of the protein particles, and its action was not specific; its effect could also be produced by certain synthetic organic preparations of sulphur. Insulin was an excellent antidote against any powerful dehydrator. An acute bacterial infection might cause such profound dehydration as to call for insulin, the drug best suited to bring back to the colloidal state those protein particles which were passing into true solution. Insulin could also be employed with advantage in cases of anæmia associated with a great destruction of the red blood corpuscles. With regard to ageratin, he said he did not know anything of the chemistry of the compound, but its clinical behaviour suggested that it might be a phosphatide, related to cephalin. Ageratin protected an animal against infections, interfered with the antigenic action of the organic extract in the Wassermann reaction, and reduced the precipitating effect of a positively reacting serum. When once in the system, this drug should prove useful in protecting man against the invasion of parasitic and chemical reagents.

Dr. M. B. RAY dealt with the early beliefs associated with the influence of various foods and drugs on the health and endurance of the individual, and expressed his belief that the ductless glands exerted a powerful effect on the body metabolism. He pictured various types of case which were held to be significant of deficiency in one or other of these important secretions, laying particular stress on the relation of goitre to rheumatism in young girls of 10 to 15 years of age. He said that in localities where goitre was endemic, the incidence of rheumatic fever, cardiac rheumatism, and rheumatoid arthritis was abnormally high.

Dr. LANGDON BROWN, in the course of his brief reply, said it would be agreed that there was now less difference between the clinical and laboratory points of view than a few years ago. Some laboratory work was beginning to confirm what some had already concluded from their clinical experience, and he asked whether Prof. Swale Vincent still took the agnostic view about the pituitary gland secretion. He regarded Mr. Leslie Pugh's remarks as of great interest; the restoration of the stimulating action of the pituitary body on the milk production of the cow by giving pituitrin showed here, as in the human, the relation between the sympathetic nervous system and the ductless glands.

Prof. SWALE VINCENT, responding to the Chairman's cordial invitation to reply, said the fact that one could extract an active juice from the pituitary gland meant nothing more than that such a juice could be extracted. There was the same lack of exact knowledge concerning the adrenals. He was not favourably impressed by the observations of Mackenzie Wallis on the blood-sugar curves, and he was unfavourably impressed by those of Prof. Dixon. Often the physiological material used was much too delicate, as also were the doses. Much more scepticism was needed by the practising physician on these matters. One never knew what would happen if a certain treatment were not adopted, and until the normal curve and incidence of a disorder was known it was dangerous to assume that a certain remedy given had been efficient, and especially dangerous was it to give a mixture, as was often done, and attribute a result to one particular component of that mixture. There were many pitfalls in therapeutics, and in endocrinology more than in any other department.

SECTION OF LARYNGOLOGY.

PAROXYSMAL RHINORRHŒA.

ON April 3rd the Section devoted itself to a discussion on the subject of paroxysmal rhinorrhœa, instead of the usual examination and consideration of cases.

Dr. JOHN FREEMAN, in introducing the subject, took as the typical condition to illustrate his remarks, hay-fever. This occurred at a certain period of the year in people whose mucous membranes were extremely sensitive to grass pollen, which produced a violent reaction in the nose, with a copious watery discharge. He was not himself sensitive in this way, and he was able to put into his veins 20 times the quantity of grass pollen that would kill a sensitive person, and yet feel no effects from it. 500 units of pollen extract would probably kill a hay-fever subject, but 20,000,000 units had no effect on the rabbit. Therefore the condition could not be a toxic one. Other forms were cat asthma, horse asthma, flour asthma, in all of which the essential was the presence of a protein irritant. Spores of fungi in infinite variety could also produce an analogous state of affairs in those who were sensitive to those substances. The irritants could reach the person either via the mucous membrane or through the blood. A colleague agreed to be rendered sensitive to pollen conveyed through the air, and the speaker tried to render himself sensitive to egg. His colleague's case was quite a success, but his own was a practical failure, as he had employed too much cocaine in the process of preparation. Practically all the sufferers from this form of rhinorrhœa he had questioned—some 500—agreed that their worst troubles were in connexion with the eye; others of less moment being the irritation of the nose, mouth, and skin, with some tickling in the throat. If, in a sensitive person, the pollen were brought to a scratch or abrasion, urticaria and a surrounding flush would be seen, and even a whole limb might swell in consequence. If repeated on a normal person, nothing happened. If the substance were put into a sensitive person's food or drink, diarrhœa and faintness would be experienced. One investigator put pollen up the rectum, and pruritus ani occurred. Angio-neurotic œdema followed putting it into a vein. Other conditions which might occur were giant urticaria, asthma, migrainous headache, epilepsy; also arthritis, colitis, and nephritis in paroxysmal attacks. Thus the effect of the substance which set up the irritation might be very widespread, though the rhinorrhœa was probably the most obvious manifestation. Mostly, heredity was very strongly marked in the subjects of this disorder, with great delicacy of nerve response, but Dr. Freeman did not regard the nervous systems of these people as abnormal. To expect to immunise against all the possible varieties of the condition was impossible; moreover, the subjects were sensitive not to one form of irritant, but to a dozen.

Dr. Brown Kelly (Glasgow) expressed his preference for the title "vasomotor rhinitis," as paroxysmal rhinorrhœa connoted only one aspect of the disease. The vasomotor disturbance in the nose was manifested by paroxysmal sneezing, profuse hydrorrhœa, and excessive swelling of the inferior turbinates. After the watery discharge ceased the nose usually became blocked by a turgescence of the erectile tissue, and the symptoms usually passed off as suddenly as they arose. It differed from a cold in the head in not being due to infection, not being infectious, and not being followed by a discharge of muco-pus. Sometimes, when the patient came for advice, all that remained of a vasomotor disturbance was swelling of the nasal erectile tissue. In these cases the intranasal appearances were often normal between attacks, but during the examination of the patient the condition of his nervous tension must be noted by the observer. If an old-standing pronounced case were examined during the swelling of the inferior turbinates, it would be seen that the swelling extended to the whole depth, whereas in rhinitis only the lower part might be enlarged. Such nasal diseases as turbinal congestion and hypertrophy, polypus, and septal deviation might be associated with vasomotor instability and might mask its manifestations. Occasionally the aspergillus fungus gained entry into the nose, producing on the posterior part of the middle meatus a tough, greenish mass of mucus largely composed of the mycelia of the aspergillus. Some patients with polypi stated that for years before the polypi formed they suffered from vasomotor symptoms. The recurrence of the polypi was largely influenced by the state of the vasomotor mechanism for the time being. It was very important to treat vasomotor instability when present, otherwise many operations might be performed without benefit. He had seen patients who derived no benefit from resection of the septum and the removal of the greater part of both inferior and middle turbinates improve quickly under constitutional treatment.

Dr. Kelly said a hypersensitiveness of the nasal mucous membrane was the local condition which in most cases predisposed to the sneezing, the rhinorrhœa, and the turbinal swelling. To reduce the nasal hyperæsthesia he had frequently used alcohol injections into the regions traversed by the two principal nerve trunks, and the success of it in many cases justified its continuance. He believed that the alcohol acted as a nerve block. The peculiarly sensitive condition of the mucous membrane he considered to be oftenest due to nerve exhaustion of emotional origin, and favourable conditions were prolonged anxiety or apprehension, and a lowered state of the general health, sometimes the latter being brought about by some form of toxæmia, or by sexual excess or irregularity.

Dr. James Adam (Hamilton) said his conclusions concerning the disorder were based on an analysis of 850 cases of asthma. Paroxysmal rhinorrhœa connoted two things, catarrh and spasm, and they were common, together or successively, in the whole respiratory tract. They were due, in his view, to toxæmia, largely as a result of dietetic and hygienic errors. The recurrent bronchitis of children ended, unless prevented, in asthma. Of the 850 cases of asthma he had analysed, 42 per cent. began in the first decade, attacks of laryngismus having been a common precedent. Manifest dietetic and hygienic errors were found in 92 per cent. of these cases of the first decade, and in 77 per cent. of cases which had started before the age of 50. Half of the 42 per cent. of cases arising in the first decade gave a history of eczema. Rhinorrhœa, laryngismus, urticaria, epilepsy, goitre, and Raynaud's symptoms were all more or less frequent complications of asthma. He contended that his toxæmia view was supported by the fact that 75 per cent. of the cases were cured by attention to diet and hygiene, chiefly outdoor exercise, and a weekly mercurial and other simple drug treatment, provided any sources of sepsis were attended to. Twenty men who had had asthma during most of their lives lost it while living under army conditions, but it returned on their resuming the softer civilian life. Veterinarians could produce broken wind in any colt by bad feeding. Asthma was sometimes complicated by epilepsy. He had cured, he said, at least half a dozen cases of paroxysmal rhinorrhœa, some of them complicated with asthma or hay-fever, by simply stopping the ingestion of milk. In fully 60 per cent. of his total number of asthmatic patients there was a nasal condition which required rectification. Chloral would stop hay-fever. The latter was not quite the same condition as asthma, for only 7 per cent. of asthmatics had hay-fever, and only 7 per cent. of hay-fever patients had asthma.

Results of Operations.

Miss Margaret C. Tod, clinical assistant at Edinburgh Royal Infirmary, reported the results of an inquiry she had made as to the results of treatment, including operations, for asthma in patients attending the clinics of Dr. Logan Turner and Mr. J. S. Fraser, as well as private cases of Mr. Fraser. Cases of asthma had been examined totalling 507, and 315 operations had been performed on them. Seven patients reported that they were worse after the operation. In 173 cases of all ages, 19 were cured, 76 improved, 78 were no better. The prognosis was distinctly better in young people than in older patients. Miss Tod also showed a table giving the results of various operations that had been performed: 38 out of 60 patients were no better after cauterisation, 19 were improved, 18 out of 51 were no better for submucous resection of the septum, while 15 out of 45 were no better after tonsils and adenoids had been removed. When operating for the relief of symptoms of asthma the patients should be told that a cure could not be promised. When the air-way was blocked, or there was an obvious focus of infection, operation often relieved the symptoms, and in young people it might result in a cure.

Dr. M. Culpin said the kind of conditions under discussion were parallel to phobias.

Sir James Dundas-Grant spoke of the beneficial effect of adrenalin in these cases. Most asthmatic patients had a small swelling of the middle turbinate body, which was extremely sensitive. Sometimes a small mobile polypus caused more irritation than a nose full of polypi. Dixon and Brodie showed that the upper and posterior part of the septum was the most sensitive in the production of reflex spasm. Some patients with vasomotor rhinitis showed a tendency to urticaria and to bruise readily; they also suffered from cold feet, chilblains, &c., conditions indicating a deficiency of calcium in the blood. Hence the importance of giving these patients calcium and magnesia.

Dr. Cocke said he had seen considerable benefit result from cauterisation of the septum and turbinals, but in children the most important treatment was the removal of septic tonsils. Possibly too much attention was being concentrated on the nose in this disease, while the whole system was largely ignored. Colloidal changes in the blood seemed to be of more importance than the local condition of the nose.

Mr. H. Banks-Davis said he usually found the blood pressure of these patients was abnormal, either too high or too low.

Mr. C. A. Parker spoke of cases in which people had been extremely sensitive to the irritation of mahogany dust. Some chair-makers in High Wycombe showed this, and they had profuse rhinorrhœa. In this case the cause seemed to be a mechanical irritation and not a question of protein.

Dr. A. Wylie said he considered that in the majority of the cases the condition was due to auto-intoxication, and attention to the general health would probably cure the patient. He believed in 1/10 gr. calomel every day in these cases.

Mr. W. Stuart-Low spoke of the value of cocaine in these cases, 10 per cent. used freely. He had never seen poisonous effects from it. He had found in these patients a sensitive œdematous spot high in the ethmoid region. It bled readily and was often a site of purulent material.

Mr. J. S. Fraser said his feeling was that this condition was one for team-work in the profession. What was specially required was that a dozen cases should be thoroughly investigated from every point of view, on the same lines as they were worked at in the Rockefeller Institute in America.

The openers briefly replied, Dr. Kelly pointing out that many of his cases had had the kind of team investigation which Mr. Fraser recommended.

LIVERPOOL MEDICAL INSTITUTION.

At a pathological meeting on March 19th at the Institution Mr. H. C. W. Nuttall read a paper on

Melanomata.

After discussing the normal distribution of melanin pigment and its relation to the pathological process, a brief description of the clinical characters and course followed. The dangerous nature of an irritated mole was emphasised and the extreme rapidity of recurrence after incomplete excision was pointed out. The histological appearances of melanomata and the difficulty of deciding the serious question as to whether they were benign or malignant was next touched upon. An analysis of 35 cases illustrated many of the points discussed. Without going into the details of the controversy, Mr. Nuttall reviewed the question of the origin of melanomata from either epidermal or mesoblastic cells, and showed that recent work was strongly in favour of an epidermal origin. A brief survey of the phylogeny and functions of the melanin pigment cell inclined to the view that, in white races at any rate, it was probably a vestigial structure and therefore more liable to atypical growth.

Dr. Roby Jones and Prof. Ernest Glynn communicated a short paper on

Blood Groups.

They had searched for abnormal blood groups among 40 medical students, mainly by cross-agglutination tests but also by absorption tests. In the former the sera and corpuscles of each student were tested against those of the remainder, making 1600 tests in all. Each test was done in five dilutions by a macroscopic method. Many difficulties had to be surmounted in keeping the sera and corpuscles sufficiently long for the tests. Numerous controls were carried out. The cross-agglutination test showed 7 per cent. Group I., 30 per cent. Group II., 17 per cent. Group III., and 46 per cent. Group IV. Abnormal agglutinations occurred in moderately high titre with four sera, three being Group IV. and four sets of corpuscles, and three being Group IV. The blood from one Group IV. student behaved abnormally both in its sera and corpuscles. Another abnormal Group IV. serum was discovered by absorption test. The relatively large percentage of Group IV. students—i.e., universal donors—whose corpuscles agglutinated slightly was striking and of considerable importance in blood transfusion.

At the last ordinary meeting of the Institution the members of the Manchester Medical Society were guests and contributed the programme.

Mr. J. B. Macalpine read a paper, with lantern illustrations, on the treatment of

Vesical Papilloma

by cystoscopic methods, combined with diathermy. He outlined his own technique, laying emphasis on the desirability of general anæsthesia in order to increase the length, and so diminish the number of treatments. In America and on the Continent, where local anæsthetics were in use, treatments were often over a dozen in number, whilst in the speaker's practice it was very rare for more than four sittings to be required. Further, the burning of the base of the growth was painful, and therefore might be shirked when local anæsthesia was employed. The per-urethral approach was, he thought, universally accepted as the method of choice in all cases where the growth was small, or where little recurrences were noticed early. With extended experience it was possible to employ it on papillomata of greater size. Even when a large growth filled a considerable portion of the bladder and rendered the examination and treatment difficult, it was usually possible for the experienced cystoscopist to select a spot where the current could be applied with perfect safety, and even though the visibility became poor as the result of cloudiness of the medium, much progress could be made, with the result that in three weeks' time, when the bladder was reinspected, the growth would have shrunk and treatment could be continued under direct vision. Such probationary treatment had proved eminently satisfactory in the speaker's experience. The results were excellent if the cases were systematically followed up for a period of two or more years. To obtain this end the patients had to be communicated with before their treatments fell due, and when many patients were simultaneously under treatment this involved a properly organised "follow-up." Such a system was illustrated in the lecture. Re-examination cystoscopies should be made at first over a period of three months, and later at six-monthly intervals. This, together with the obtaining of the cases at the first onset of hæmaturia, was the secret of good results. Recurrences when recent were easily and successfully treated. It was an interesting fact that return growths rarely took place on the site of the primary at a period later than three months from the last treatment.

Prof. A. Ramsbottom then read a paper on Dizzy Attacks.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

A meeting of this Society was held on April 2nd, Dr. E. F. Maynard, the President, in the chair.

Mr. F. E. Feilden read a paper on

Cystoscopy.

He said that cystoscopy was one of the most important methods of exploration in urological surgery. In cases of vesical calculus cystoscopy gave a correct diagnosis and indicated the correct method to adopt for the removal of the calculus. As to whether an anæsthetic was required or not depended upon the circumstances of the case; usually no anæsthetic was required. *Bacillus tuberculosis* or *B. coli* might be found in the urine without any lesion of the kidney being present. Residual urine, a trabeculated bladder, and no evidence of urethral obstruction usually indicated some lesion of the cord. The experiments of S. C. Dyke and B. C. Maybury seemed clearly to indicate the caution that was necessary in pyelography and irrigation of the kidney pelvis. Cystitis due to the gonococcus, he held, was not common. In estimating the functional activity of the kidneys the most reliable test, in the speaker's opinion, was the urea-concentration test, but also the blood cholesterol content would appear to be of value. Too often cases of frequency were treated on expectant lines, when early cystoscopy might prevent irreparable damage to the bladder wall. Meatoscopy in certain cases was useful in diagnosis, but this was not so in the majority of cases. Growth, stone, and tubercle were more common on the right side; this might be due to the fact that there were more structures crossing the right than the left ureter. To X ray a patient with a ureteric bougie in situ was a valuable means of differentiating between a calculus in the ureter and a calcareous gland adjacent to the ureter. Not infrequently the failure of a nephropexy was due to the kidney not being fixed at a sufficiently high level. A double ureter should suggest other abnormalities in the urinary tract. In catheterising healthy ureters when the bladder was known to be infected there was little likelihood of conveying the infection to the ureters. Nephrectomy in cases of hæmaturia of unknown origin was only justifiable when the bleeding was unilateral, or when by its frequency or amount it endangered the patient's life or seriously interfered with his occupation. In selected cases diathermy through the cystoscope was a most successful procedure, obviating the prolonged convalescence that was often associated with an open operation. In the course of his remarks he said that the best cystoscope now on the market was one of German or American manufacture. It was advisable to get accustomed to an instrument of known magnification and endeavour to distend the bladder with a uniform quantity of fluid.

Dr. **GEORGE MORGAN** quoted a case of varicose veins of the prostate with severe attacks of hæmaturia every three months lasting two to three days which cleared up with capsules containing turpentine (2 minims) taken every four hours. He also quoted a case which was diagnosed as a small stone in the ureter by X ray but which, on cystoscopy, was shown to be an old calcareous gland.

Dr. **H. M. GALT** considered that there was no difficulty in eliminating *B. smegma* with modern bacteriological staining methods when examining urine for tubercle bacillus.

Mr. **M. FITZMAURICE-KELLY** considered that cystoscopy should be done under a local anæsthetic in males. In females an anæsthetic was not required. In cases of severe cystitis he considered that spinal anæsthesia should be employed also. In advanced tuberculous kidney, when it was important to know the function of the other kidney, spinal anæsthesia was very valuable when using indigo-carmine test for renal efficiency. In renal lavage it was quite safe to use a pressure of 15 inches—i.e., below secretory pressure. Where there was difficulty in diagnosis between stone and tumour, a ureteric catheter could be used as a probe. Bleeding from one kidney might be caused by malignant disease, and it was very important to diagnose the condition and operate at once. For this pyelography should be employed to show the filling defect of pelvis.

Exhibition of Case.

Mr. **FITZMAURICE-KELLY** showed a case of Epithelioma of the Bladder. The patient, a woman aged 54, had no symptoms till Sept. 26th, 1923, when a sudden large hæmorrhage from the bladder occurred. This was followed by retention due to clots, necessitating catheterisation. Cystoscopy on Sept. 27th showed a papillomatous growth on the anterior wall of the bladder. At operation on Sept. 29th a hard, flat ulcer was found just above the papilloma, and the whole thickness of the bladder wall bearing the growths and an area about three-quarters of an inch around was resected, and the bladder closed with drainage. Two applications of radium, 140 mg. per 12 hours, were made on Oct. 6th and 7th through the suprapubic opening. Now, 18 months after the operation, the patient remained well and free from symptoms. In connexion with this case Dr. Galt showed some excellent microscopical slides.

Reviews and Notices of Books.

DIGITALIS.

The Action and Uses in Medicine of Digitalis and its Allies. By A. R. CUSHNY, M.A., M.D., LL.D., F.R.S., Professor of Pharmacology in the University of Edinburgh. London: Longmans, Green and Co. 1925. Pp. 303. 18s.

THIS volume is written in Prof. Cushny's usual lucid and comprehensive style and will be a welcome addition to medical literature. The author's wide clinical experience and 30 years of continuous interest in the subject of digitalis enable him to view the recent advances in true perspective. The chapter on the changes seen in the course of the therapeutic application of digitalis is admirable. Beginning with a critical historical introduction, the book deals with the known facts of the chemistry of digitalis and considers at length the information which laboratory experiment has collected from a study of its effects on the heart of the frog and the mammal. The action on the blood pressure and on the central nervous system is described and a chapter is devoted to the important matter of the absorption, cumulation, and elimination of digitalis bodies.

There are many fields in which pharmacology has, in the last 25 years, been able to modify or illuminate the clinical path, but it seems that in this particular subject the cardiographer investigating patients has made greater progress than the laboratory worker. The book reveals a story of failure to isolate the active principle from digitalis or do more in analysis of its action than observe the effect of toxic doses on the heart in vitro. The removal of œdema fluid, perhaps the most striking clinical effect of digitalis, has not as yet received satisfactory experimental investigation. A final chapter deals with the administration and biological assay of digitalis. The introduction of biological tests for therapeutic agents whose activity could not be determined chemically was due to Houghton in America, who proposed one for digitalis. The value of these tests in the case of other preparations, such as pituitary extract, insulin, and neosalvarsan, is fairly well supported by clinical evidence. In the case of digitalis only there is no evidence to support the biological test—that is to say, the clinician does not encounter samples which are either uselessly weak or dangerously strong, and he is unable to distinguish between preparations which the laboratory test declares to be widely different in potency.

The discussion on dosage should prove useful, for too little is known in this country of the treatment devised by C. Eggleston in America, whereby excellent effects are obtained in many cases through the administration of large doses, such as 2½ drachms, over a short period of time. A valuable bibliography concludes the book.

OPERATIVE SURGERY.

By W. S. BICKHAM, M.D., F.A.C.S., former Surgeon in Charge of General Surgery, Manhattan State Hospital and Instructor in Operative Surgery, College of Physicians and Surgeons (Columbia University). Vols. V. and VI. London and Philadelphia: W. B. Saunders Company. 1925. Pp. 880 and 980. 50s. per volume.

THESE two volumes complete this large system of operative surgery. The general plan and scope of the work have been referred to in our reviews of the first four volumes. Volumes V. and VI. maintain the high standard which characterises the earlier parts. We congratulate the author on having been able to carry through to completion such a great task without showing any obvious sign of fatigue or staleness. The subjects treated in Volume V. are operations upon the colo-recto-anal tract and the genito-urinary system in the male; in Volume VI. those upon the female genital organs and the new-born are considered, and indeed this volume forms a complete treatise on operative gynæcology. A final chapter is devoted to some operations which are not described elsewhere. The same encyclopædic outlook is evident in these volumes as in the rest of the work. Thus there are described five methods of valvotomy of the valves of Houston for fæcal obstruction.

The various operations for hæmorrhoids occupy 42 pages, whilst for complete rectal prolapse 11 different methods are given. This last example illustrates very well what some might regard as the greatest defect of the book. Every practising surgeon knows how difficult it is to cure some of these patients with prolapsus ani permanently. Therefore he seeks guidance as to the results likely to be got from the different procedures. The author gives him but little help in choosing the most beneficial method for any particular case. Once having selected an operation, however, the reader can be sure of finding it well and clearly described. We notice that certain cystoscopic techniques concerned with bladder growths and ureteric calculi are not included amongst the other operations upon these organs. A separate index volume is issued, and seems to be very complete. "Bickham's Operative Surgery" covers the whole field of operative surgery fully and systematically and is likely to take its place as a standard work of reference on operative technique.

GYNÆCOLOGY AND MIDWIFERY.

1. *A Practice of Gynæcology.* Fifth edition. By HENRY JELLETT, M.D. Dub., F.R.C.P.I., Consulting Obstetrician to the Department of Public Health, New Zealand; Ex-Master, Rotunda Hospital, Dublin. London: J. and A. Churchill. 1925. With 417 illustrations and 12 coloured plates. Pp. 744. 25*s.*
2. *A Short Practice of Midwifery.* Ninth edition, revised. Same author and publishers. 1924. Pp. 591. 18*s.*
3. *A Short Practice of Gynæcology.* For Medical Students. Fifth edition. Same author and publishers. 1924. Pp. 438. 18*s.*

1. A FOURTH edition of the Practice of Gynæcology appeared in 1916, and the present edition shows that careful and extensive revision have been since carried out by the author. A number of fresh sections have been added, amongst which those on gas inflation of the peritoneal cavity and of the Fallopian tubes, ovarian transplantation, and the Manchester treatment of uterine prolapse and implantation adenomata of endometrial origin deserve special mention. The chapter on menstruation and its disorders has been largely rewritten and brought into conformity with modern views on these subjects, and a similar course has been adopted in regard to that in endometritis and metritis. New chapters have been added on sterility and on the general principles which govern gynæcological operations. The cauterisation of the endometrium by means of superheated steam has been almost universally abandoned and replaced by surgical methods or by radiotherapy. The author wisely dismisses with a few words the subject of atmocausis and zestocausis, to which some attention was given in the fourth edition. The revision of the book and the choice of new matter have been careful, and the whole forms a complete and good text-book which should be appreciated by students.

2. The appearance of a ninth edition of the same author's "Short Practice of Midwifery" is an indication of its value. For each condition a definite line of treatment, which has been found successful in the very large experience of the Dublin School, is given. In a few instances the views expressed do not correspond with those of the majority of writers of other schools. For example, the statements that the beginning of labour is the best time to perform version in breech presentation, and that "prophylactic pubiotomy" is the method of choice in the treatment of moderate degrees of pelvic contraction, are not in accord with the teaching of other schools; again, most English and American obstetricians advise against the use of Schultze's method of artificial respiration in white asphyxia of the new-born. No mention is made of intracranial birth injuries or the causes of stillbirth generally, nor is the occasional value of X rays in obstetrical diagnosis noted. Ante-natal examination and post-maturity are two subjects which perhaps are worthy of more emphasis than they receive. But the book as a whole can be thoroughly recommended, and should be especially valuable to the junior practitioner.

3. A fifth edition of the smaller manual, "A Short Practice of Gynæcology for Medical Students," has also been prepared by Dr. Jellett, its title indicating that it forms an introduction to the science. In this edition several minor alterations have been made and the chapter on endometritis has been entirely rewritten. The book still retains its strictly anatomical arrangement. We are not satisfied that this is advantageous in a manual for students, since the far-reaching consequences of an infection, for example, with the gonococcus, are not effectively presented. Displacements of the uterus are fully considered, the description of the mode of production of prolapse following the older school. In the list of causes of retroversion of the uterus it is not made sufficiently clear that these conditions do not necessarily cause retroversion. No mention is made of the congenital variety. Most modern authorities would not agree that retroversion need be treated except in the minority of cases. Throughout the book the sections on treatment are good. Conservatism in operative work is strongly advocated. The volume is well illustrated, particularly the chapters on operations.

THE PARKINSONIAN SYNDROME.

Les États Parkinsoniens et le syndrome Bradykinétique. Par MM. HENRI VERGER et RÉNE CRUCHET. Avec la collaboration de MM. D. ANGLADE et A. HESNARD. Paris: J. B. Baillière et Fils. 1925. Pp. 206.

THIS little work contains the substance of six lectures delivered in the Medical School of the University of Bordeaux, and expresses the views of the authors concerning the clinical symptomatology and pathology of the Parkinsonian syndrome which may ensue after an acute attack of epidemic encephalitis. It may be regarded as an expansion of Prof. Cruchet's recent lecture at the Royal Society of Medicine on the same theme. The lectures are vividly written; the authors' use of the historic present in describing illustrative cases reproduces the atmosphere of the clinic, and the arguments in favour of their contention that the syndrome is a thing apart from chronic paralysis agitans are lucidly expressed. In this matter many will agree that the views of Netter and Souques as to the possibly similar ætiology of the two disorders cannot yet be abandoned, despite the skilful pleadings of the Bordeaux school. The important physiological work of Sherrington and of I. Hunter has thrown much light on the pathogenesis of the Parkinsonian syndrome. The book is well illustrated by photographs and microphotographs.

PHYSICS.

Spectroscopy. By E. C. C. BALY, C.B.E., M.Sc., F.R.S., Grant Professor of Inorganic Chemistry in the University of Liverpool; Fellow of University College, London. London: Longmans, Green and Co. 1924. Pp. 298. 14*s.*

THE third edition of this book is to appear in two volumes; the first of these contains an historical introduction of 40 pages, and is devoted largely to technique. Therein can be found information upon practically any aspect of technique involving the spectroscope, the spectrometer, and the different forms of diffraction grating, though the crystal gratings appropriate for very short wave-lengths do not come within the author's range. Perhaps the information derived from those atomic gratings will receive some consideration in Vol. II. The author has had much experience of practical work on his subject and is able on this account to indicate the many pitfalls which await the investigator in the study of the various types of spectra. With this mass of information before us as to the methods which have been proved appropriate to the different regions of the spectrum we await with interest the author's concluding volume describing the important results which have been obtained by their use.

New Theories of Matter and the Atom. By ALFRED BERTHOUD, Professor of Physical Chemistry at the University of Neuchâtel. Translated from the French by EDEN and CEDAR PAUL. London: George Allen and Unwin, Ltd.; New York: The Macmillan Company. 1924. Pp. 259. 10*s.* 6*d.*

Prof. Berthoud reminds us that 25 years ago practically nothing was known about the structure of atoms; now studies of atomic structure are being carried out in many physical laboratories. This book gives a detailed account of the advances in knowledge which have made this possible, especially in their general relation to the problem of the constitution of matter. The treatment of the subject is on an ample scale and mathematical analysis is supplied when occasion requires. An extremely interesting account of isotopes and the bearing of atomic structure on chemical affinity is included. The translators have done their part well. This account of modern discoveries in physics and chemistry deserves to be widely read.

The Vacuum. By J. A. COCHRANE, B.Sc. London: G. Bell and Sons, Ltd. 1924. Pp. 103. 1*s.* 6*d.*

IN this book the author follows on the same lines as those which make his "Readable School Physics" so attractive. After a brief account of early ideas on the subject of the vacuum, Mr. Cochrane gives an interesting description of the work of Torricelli, von Guericke, and Pascal. He then discusses the many ingenious devices for the attainment and measurement of various degrees of gaseous rarefication. In describing the limits of use of the ordinary water-jet aspirator, the author says: "The water, however, does not carry all the air in the outer vessel with it, and therefore it is not possible to obtain a very high vacuum with this instrument." This explanation is hardly satisfactory, but such blemishes are few in a very attractive little book.

THE SUCCESSFUL PHYSICIAN.

By VERLIN C. THOMAS, M.D., Visiting Physician to Franklin Hospital, San Francisco. London and Philadelphia: W. B. Saunders Company. Pp. 303. 18*s.*

THIS book has been written for the young practitioner to fill the gap between theory and practice. It is acknowledged that whatever other experience awaits the young doctor he will find a sharp contrast between his college and hospital life and the life that confronts him outside. Dr. Thomas has spared no pains in his efforts to point the way towards success, nor has he failed to warn the unwary of many pitfalls. The manner in which much sound observation and useful commentary is presented may be somewhat distasteful to the English reader. For example, such chapter headings as How to Attract and Hold Patients, and Changing Ability into Income are jarring, because they seem to put emphasis on the commercial side of a calling that cannot be carried on as a trade. But to every practising doctor business considerations must be of importance, and Dr. Thomas has set up certain guide posts which are likely to be of real value to the newly qualified. He regards a sound scientific equipment as an indispensable foundation. An important consideration is the choice of a locality favourable for the development of the type of practice which the young practitioner aims at establishing. Personal qualities essential to success are integrity, a sympathetic knowledge of human nature, and the power to inspire the particular patient with that confidence which plays so large a part in the science of healing. Among other useful homely precepts we find, "Remember what you say to your patients and see that your later statements agree with your first. You will have many to remember and he has only his own case to keep track of—and will remember all you tell him." This is a strong argument for keeping careful notes. Again, "Telephone your convalescents and inquire of their progress. If they are going on a long journey, ask them to write you of their condition." A simple direction like this is prompted by a sound view of human psychology, while many a patient would be saved future trouble, and incidentally expense, by thus keeping in touch with his medical adviser.

SURGICAL DIAGNOSIS.

Allgemeine und spezielle chirurgische Diagnostik. Ein Lehrbuch fur Studierende und Arzte. Von Prof. Dr. MAX KAPPIS. Berlin: Urban and Schwarzenberg. 1924. Pp. 625. G.M.15.

IN this book Prof. Kappis offers to surgeons the results of many years of observation both by himself and by his colleagues. The cases he records have been studied with the thoroughness and the infinite attention to detail which appear to be the peculiar quality of the German mind. The result is a vast collection of original observations, admirably systematised and arranged, so that the experiences and the records of the Hanover Clinic on almost any conceivable detail of surgical diagnosis are instantly available. The illustrations would render the volume a valuable possession to a surgeon even if he were ignorant of the German language, but the concise descriptions of different conditions and their differential diagnosis should not be missed. The book is a record of vast experience, and any surgeon will turn its pages with delight.

GENERAL SYSTEMATIC BACTERIOLOGY.

Monographs on Systematic Bacteriology. By R. E. BUCHANAN, Ph.D., Professor of Bacteriology, Iowa State College, U.S.A. Baltimore: Williams and Wilkins Company. 1925. Pp. 597. 30*s.*

THIS is the first of a promised series of monographs, in the general field of systematic bacteriology, which should ultimately constitute a valuable reference library. This volume—a large one—represents an immense amount of labour and research into literature in an extremely specialised field, but a considerable number of further volumes may be expected if the whole subject is to be adequately covered. Dr. Buchanan gives us an exhaustive review of nomenclature divided into three parts, of which the first, consisting of 108 pages, deals with the history of attempts at systematisation from 1773-1923; and the second, containing 42 pages, is devoted to a discussion of codes of nomenclature and the formulated rules of various botanical, zoological, and bacteriological societies. The third, and major part of the book, consists practically of a dictionary of generic names that have been at various times put forward in bacteriological nomenclature, tracing them from their origin, through the various vicissitudes of their existence, up to their current use. Any worker in doubt as to what is really meant by such terms as myco-bacterium, leuconostic, nocardia, and other such loosely-used and ill-understood words, will find a complete history of each term, with references to its use and abuse by different writers of all nationalities. The work throws many curious lights upon the science of bacteriology, and while it reveals the awful confusion of bacterial nomenclature, it also shows the prolixity of the lesser men and the extent of their obsession by the importance of names. The great masters of the science have contributed little or nothing to the confusion which Dr. Buchanan catalogues: Pasteur appears in but two connexions, and Koch not at all.

The volume is a valuable contribution to the literature of its subject, and will be of the highest use as a work of reference to any systematic bacteriologist.

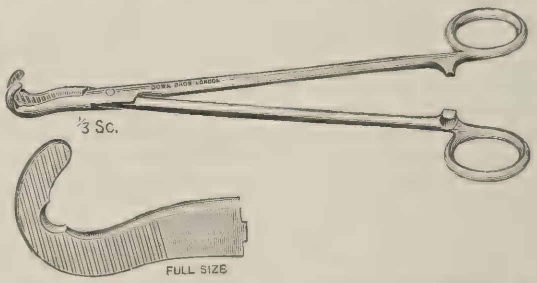
JOURNALS.

BRITISH JOURNAL OF CHILDREN'S DISEASES. Vol. XXII. January–March.—Dr. F. G. Chandler and Mr. T. W. Preston contribute a paper on pulmonary tuberculosis in childhood based on the study of nearly 300 cases which had been seen at the City of London Hospital for Diseases of the Heart and Lungs during the last 12 years. Although the diagnosis of pulmonary tuberculosis was definitely proved in only 89 by finding tubercle bacilli in the sputum or by post-mortem examination, it is probable that the remainder were early cases of pulmonary or possibly hilum tuberculosis. The ages of the 89 patients whose histories are given in tabular form ranged from 3 to 14 years. In all the cases the lungs, or perhaps the mediastinal glands, were primarily affected. No examples of miliary tuberculosis were included with the exception of three children, who were admitted with obvious pulmonary tuberculosis and died of a terminal miliary affection. Sixty-one, or 68·5 per cent., were females and 28 were males; 39 were 12 years and under, and 22 were 10 years and under. As the result of treatment, 35 were improved, 19 were discharged with the condition unchanged, 27 died, and two were still in hospital. The writers' conclusions are as follows: Pulmonary tuberculosis does occur in childhood and infancy and is not extremely rare. It may run a long, chronic course and is not necessarily fatal. The stronghold of the disease is at the bifurcation of the trachea and bronchial glands, and the lungs are probably infected from this source. Before a diagnosis of intrathoracic tuberculosis is made, every care should be taken to exclude other chronic infections, but when this has been done there should not be too great a reluctance to diagnose tuberculosis, especially when symptoms such as cough, febrile attacks, and poor nutrition are predominant features.—Dr. F. J. Poynton and Dr. L. B. Cole report a case of cœliac disease with glycosuria in a boy, aged 7 years, which was of interest in that there were associated in the same child two profound disorders—an inability to absorb fat seen typically in cœliac disease and an inability to utilise carbohydrates seen typically in diabetes mellitus.—Dr. Donald Paterson and Dr. W. G. Wyllie describe a case of hypertrophy of the bones of a limb due to a nævus. The patient was a boy, aged 7, in whom a nævoid condition of the vessels round the right knee-joint was associated with inequality in length of the lower extremities, the right leg being one inch longer than the left.—Dr. E. W. Goodall records a case of orchitis and abdominal pain occurring as a complication of serum sickness. The patient was a boy, aged 10 years, who had received 33,000 units of diphtheria antitoxin in three doses for a severe attack of faucial and nasal diphtheria. Fourteen days after the last injection and one day after the appearance of serum arthritis and pyrexia he complained of pain in both testes, which were slightly swollen and tender. The scrotum appeared to be inflamed. He also complained of pain in the left side of the abdomen. The pain in the abdomen and testes gradually disappeared after lasting for another 12 days, during which an erythematous rash on the trunk and limbs and irregular pyrexia were present. Similar cases of orchitis and abdominal pain during serum sickness have been reported by French observers, but are very rare.—Mr. C. P. R. Gibson reports a case of intraperitoneal abscess of unknown origin, probably pneumococcal, in a girl, aged 6½, with the post-mortem findings.—Mr. Macleod Yearsley writes on otology in 1924.—The abstracts from current literature are devoted to otorhinolaryngology and treatment.

New Inventions.

FORCEPS FOR THE LIGATION OF BLEEDING POINTS IN DIFFICULT POSITIONS.

A HALF-RING artery forceps is here illustrated which facilitates the placing of ligatures on bleeding points in those situations where a pair of straight forceps have grasped the vessel and subsequent ligaturing is difficult, such as the tonsil-bed following enucleation. They are in two lengths, 6 or 8 inches, as may be required. The half-ring end has a notch on each blade which is run down to the point of the straight forceps already placed, and the forceps closed on the tissue beyond the immediate grip of the straight forceps. The straight forceps are now removed, the half-ring enables easy placing of a ligature without any danger of the vessel escaping from it when the forceps are removed.



Messrs. Down Bros., St. Thomas's-street, London, S.E., have made the instrument for me.

CHAS. JOHNSTON SMITH, F.R.C.S. Edin.,
Senior Government Surgeon, Singapore.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 28TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—Small-pox, 134; scarlet fever, 1706; diphtheria, 976; enteric fever, 30; pneumonia, 1418; puerperal fever, 53; cerebro-spinal fever, 7; acute poliomyelitis, 8; encephalitis lethargica, 82; continued fever, 1; dysentery, 4; ophthalmia neonatorum, 111. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases showed an increase of one from the number for the preceding week.

Deaths.—In the aggregate of great towns, including London, there was 1 death from enteric fever, 130 from measles, 10 from scarlet fever, 140 from whooping-cough, 28 from diphtheria, and 281 from influenza, as compared with 304, 283, 361, and 346 in the four preceding weeks. In London itself the deaths from influenza numbered 26, from whooping-cough 37, and from diphtheria 7.

ROYAL SANITARY INSTITUTE.—A sessional meeting will be held on Friday, April 17th, at 8 P.M., at the Town Hall, and Saturday, the 18th, at 10.15 A.M., at the Medical Baths, Torquay, when discussions will take place on the Necessity for a New Public Health Act; the Town Planning and Housing Scheme at Torquay; Maternal Mortality; and the Spa Treatments at the Medical Baths, Torquay. The chair will be taken by Mr. H. D. Searles-Wood, F.R.I.B.A. (Treasurer of the Institute). Those proposing to attend should notify the Hon. Local Secretary, Major H. A. Garrett, Borough Engineer, Torquay, not later than April 11th.

THE LANCET.

LONDON: SATURDAY, APRIL 11, 1925.

THE PERSISTENT VOMITING OF INFANTS.

The causes of persistent vomiting in infants are so many and so varied, ranging from "nerves" to serious anatomical defect, that the practitioner who has to deal with a case—and there is no practitioner who is safe from the menace—needs to have all his wits about him. Not only has the child to be considered, perhaps even life being in danger, but treatment has also to be directed towards the mother, whose attitude is rarely that best adapted to the situation. Indeed, there are many cases of persistent vomiting where the mother alone requires attention, the child being quite well able to recover normal habits if released from constant maleficent stimulus. But behind the mother there may loom the grandmother or mother-in-law, each feeling that her status endows her with intuition, and in many cases there will be added the voice of the child's domestic nurse believing firmly in some régime. This is not an imaginary picture; in just such a chorus the practitioner may have to decide, both quickly and accurately, the cause underlying the condition, if he is not to treat the case of organic stenosis by the methods which would be suitable for a case of rumination, or confuse a gastritis with a case of nervous vomiting.

Dr. H. C. Cameron dealt with these various conditions in the last Lumleian lectures delivered at the Royal College of Physicians of London. In recent years much has been made of the condition of idiosyncrasy to cow's milk, certain physicians abroad claiming that mild forms of this condition are the basis of all sorts of infantile dyspepsia. This explanation has not, however, been substantiated, and in Dr. Cameron's opinion the true condition is very rare and is easily recognised by the sudden pallor, drowsiness, pyrexia, vomiting, and diarrhœa following the ingestion of the smallest quantity of the foreign protein. Another uncommon condition, but one that must not be forgotten in differential diagnosis, is that of infantile rumination, which differs from the same condition in adults in that it is confined to the milk period and is the culmination of a series of voluntary movements; while here a definite nervous irritation is produced if these movements are thwarted, and an undoubted state of beatitude is induced by the successful conclusion of the manœuvre. Dr. Cameron classed rumination with thumb-, tongue-, and lip-sucking and head- and thigh-rubbing as stereotyped movements which are liable to become fixed by repetition until they are habitual. Some transitory irritation may have initiated them in the first place, but as an established habit they are associated with a lowly form of gratification which, in due course, gives place to older methods of obtaining satisfaction unless the habit is fixed by expostulations, agitation on the part of the parents, or the use of mechanical restraints, for these serve to awaken ungratified longing and to focus the attention on the infantile delight. Various treatments have been advocated, including distraction of the attention, plugging of the nostrils, and forcible closure of the mouth. All are successful in some cases; in Dr. Cameron's experience that most generally efficacious is the thickening of the food to the consistency of a thick gruel by the use of some such substance as farina. Thickened food is also useful, in his opinion, in some cases of habitual, severe, and long-standing nervous vomiting. A small amount of thick food given before the normal feed stimulates peristaltic contractions and prevents the rejection of the meal. Chloral hydrate given before the feed may be of value, the child being then made to suck while in a somnolent condition.

Dr. Cameron gave a vivid description of that "nervous infant" which is the bane of the infant welfare centre as well as of the private physician—the babe whose sleep is scanty, who is awake at the slightest stimulus, resuming a constant wailing cry, with clenched hands, hypertonic muscles, a stomach in a state of hyperæsthesia so that food of any kind leads to pain, and a sensitivity of taste which detects the slightest change in diet constituents. These babies grow up into the "nervous child," with enuresis, stammering, habit spasms, anorexia, and eczematous conditions. The dieting of this infant is a matter of great difficulty; it is useless to attempt diluted foods such as would be suitable for true dyspepsias. Often there is no malnutrition associated with this form of vomiting unless some well-meaning pædiatrist has introduced a modified or diminished diet. There does, however, seem to be a special intolerance of fats, and the reduction of fat in the milk is at times attended by successful results. The stimulation of hunger must be avoided, but the predominant factor is the environmental. Symptoms often cease like magic in hospital or in the hands of a competent and self-confident nurse. A tight shawl or a prolonged bath may rest the over-stimulated nervous system; the value of the infantile strait-waistcoat, "swaddling clothes," has long been recognised by simple peoples. Even in small infants a condition of "negativism" may be met, whereby the infant's first waking thought is to resist anything which may be done for it. The condition may persist as an inveterate neurosis for years, and the more attention there is paid to it the more inveterate it becomes. The lectures provided a valuable survey of the conditions which must be borne in mind when investigating a case of vomiting in the infant.

◆

THE MEDICAL WITNESS.

There are probably few who practise medicine or surgery who have not at some time found themselves in the witness-box in a court of law. Cross-examination has fewer terrors for them than for the average witness. They are usually present in court to speak of something of which they have made prolonged study and have special knowledge. They meet the cross-examiner on more than equal terms, and need the protection of the presiding judge less than does the non-professional witness. But some recent remarks of the Lord Chief Justice upon certain objectionable forms of cross-examination are of interest even to the expert witness. Counsel, said Lord Hewart lately in the Court of Criminal Appeal, are growing too fond of the type of question which begins, "Is your evidence to be taken as suggesting that . . . ." The really discreet witness might reply, "That is not for me to say; it is for others to draw conclusions from my evidence; I am here only to answer relevant questions, not to make suggestions." But such an answer—if the average witness had the prudence, the experience, and the self-restraint to make it—would probably damage him with a jury from its apparent excess of caution and want of frankness. Questions of this type are usually invitations to argument, the first exchanges between counsel and witness in a sparring match in which counsel is a professional and the witness as a rule an amateur. It is, says Lord Hewart, a mischievous line of cross-examination.

Expert witnesses have less to fear from questions of this nature. They come to court prepared and equipped to make suggestions, to propound or support theories and to argue about them. Nevertheless, if the sparring match goes too far, they may be glad to remember the words of the Lord Chief Justice and to seek the protection of the Court. The particular case which elicited Lord Hewart's observations deserves notice as one in which counsel on both sides had overstepped the line. The charge was one of assault under the Criminal Law Amendment Act. It is a well-known principle of English law that, when an accused person is on his trial, the prosecution must not mention anything which suggests that his character has been otherwise than good, unless the accused himself puts his own reputation too high, or unless he attacks the character of a witness for the Crown. When the accused was giving evidence on his own behalf at Manchester his counsel asked him questions indicating that he was a respectable family man. This was putting his character dangerously high, because the accused had formerly had a bastardy order made against him. Though the defending counsel had thus, in Lord Hewart's opinion, gone too near the line, the prosecution did not take advantage of the position at this stage by counter-attacking with evidence of the bastardy order. Presently, however, in cross-examining the accused man, counsel for the prosecution in turn overstepped the line by asking such questions as the following: "Can you suggest any reason why the girl should invent this story? Do you regard her story as blackmail? Do you agree she is trying to shield some boy?" Naturally, these questions lured the witness into answers which could be construed into an attack on a witness for the Crown, and the Court thereupon allowed evidence to be given of the previous bastardy order. The Court of Criminal Appeal has now held that the questions (and the use made of the answers) were unfair and has quashed the conviction.

Medical witnesses must expect the converse treatment. The cross-examiner, instead of asking them to attack the reputation of the expert witnesses whom he has called, will invite them to acknowledge their high qualifications. Here again the discreet answer is the safest. Mr. Justice McCardie has been saying that it is a very serious thing for a judge to restrict cross-examination. But forensic excess is usually staged with a jury for audience. And, even if judges will not interfere, juries sometimes find means of expressing their disapproval.

◆

RECENT RESEARCH INTO SCARLET FEVER.

It has long been something of a reproach to modern medicine that the investigation of the eruptive fevers has not progressed pari passu with the advances made in other fields. When we read the masterly accounts of small-pox, scarlet fever, measles, or typhus left by Trousseau or another of the great masters of what may be called the "clinical period," we realise, with a sense of uneasiness, that, in a day of wide application of modern methods of research, there is little which we can add to the descriptions of the processes of these diseases, as left by them There are, of course, excuses and explanations. Infectious diseases, in the interests of the community, require to be isolated, and it is a regrettable fact that pathological research is only exceptionally provided for within the walls of our fever hospitals. While this is so the very protective measures necessary for the common weal may, in the long run, defy the end in view by retarding the progress of our knowledge of infectious diseases. During the last few years the possibilities of the immense and largely untouched field of investigation which these diseases offer has been more clearly perceived, and a large amount of attention has been devoted to them, more especially in America.

Amongst the results obtained those which have an important bearing upon the question of the ætiology of scarlet fever are now being widely tested in all countries, and have achieved the notoriety of a question in Parliament this week. Researches on the value of the Dick test in the diagnosis of this disease by C. C. Okell and H. J. Parish, and by Herbert Henry and F. C. Lewis, with workers in the Birmingham fever hospitals, were recorded in our last week's issue. Since 1921 there have appeared from time to time a series of papers by Gladys and George Dick which have shed a good deal of light upon the ætiological significance of the streptococcus in this disease, and have adduced some suggestive results. It has long been recognised that this organism had a more than casual relationship to scarlet fever, but opinion has been divided as to whether it was the actual causal agent or merely a concomitant infecting organism which became increasingly active in the altered conditions produced by the disease; thus, although not responsible for the malady, it might be the cause of the suppurative complications in which it is constantly demonstrable. To assert with confidence that a given organism is causal in any disease it is necessary to satisfy certain conditions first clearly enunciated by Koch; these require that the organism shall be constantly associated with the lesions and that, when recovered from them and cultivated in a pure state, it shall be capable of reproducing the disease. This last condition is often hard to fulfil, since it sometimes requires human experiments, the diseases produced by pathogenic organisms in the lower animals often being very inexact reproductions of the disease as it spontaneously occurs in man. Hæmolytic streptococci have long been known to be constantly present in the throat in scarlet fever, and the specific and rather well-marked characters of this group were described, under the title of *Streptococcus anginosus*, by F. W. Andrewes and T. Horder in their pioneer paper on streptococcal classification in 1906. The constancy of these rather special, long-chained types of streptococci is a universally acknowledged fact, but any proof of their causal relationship more solid than mere presumption has hitherto been lacking. Of recent years there has even been a tendency to regard scarlet fever as a disease possibly due to an ultramicroscopic virus. In the absence of any direct fulfilment of Koch's third postulate, however, a considerable amount of supplementary evidence has been forthcoming to indicate a reaction between the body and the scarlet fever streptococci which may be taken to indicate an actual invasion by the latter, and hence be interpreted as indicating their ætiological significance. Further, the work of Dochez and others has tended more firmly to establish the identity and to delimit the group of streptococci found in this disease upon immunological lines. It is held, and there is considerable confirmation for this, that these organisms form a distinct and specific agglutinable group amongst the hæmolytic streptococci, and that the serum of convalescents will agglutinate hæmolytic streptococci from scarlet fever, but will fail to agglutinate the ordinary pyogenic strains.

To the separation of this group by immunological, and consequently highly specific means, there has been added direct and indirect evidence of the rôle of the organisms by the work of the Dicks. They claim to have reproduced the disease in susceptible volunteers by the inoculation of pure cultures of the organism. This work still awaits confirmation. On the side of indirect evidence they have introduced a test, akin to the now familiar Schick test in diphtheria, which consists in the intradermal inoculation of a minute amount of a toxic substance produced in cultures of the scarlet fever streptococci. This, in individuals who have never suffered from scarlet fever and are susceptible, produces a small focus of erythema comparable to the scarlet fever rash. In convalescents from the disease the reaction is usually negative, and the toxin is, moreover, neutralisable by the serum of convalescents, or by that of animals injected with the specific streptococci. Obviously the importance of this work lies not in the mere demonstration of the reaction and its possible diagnostic value, but, if the ætiological rôle of the streptococcus be proven, in pointing the way to the detection of susceptible individuals, and the production in these of artificial immunity upon similar lines to those adopted in diphtheria. The work of Okell and Parish generally substantiates these claims in so far as the condition in convalescents is concerned, since in 120 of these they found the test positive in 18 and negative in 82. Owing to the admitted uncertainties in the diagnoses it is possible that the figures for the positive results may even be too high. On the other hand, the results in a population of 95 "normal" students were largely anomalous. Here 20 persons giving a history of scarlet fever gave positive results to the extent of about 65 per cent., whilst 75 with no such history gave an incidence of 76 per cent. of positive reactions. These figures, in so small a group of persons, show no significant difference, and though it is undesirable to draw any inference from insufficient data, should these results be reproduced in an adequate number of observations it would indicate that the factor influencing the test, which is taken to represent immunity or susceptibility to the streptococcus, is not the same thing as immunity to the disease scarlet fever, which is usually a life-long affair. A further clinical test of interest in this connexion is that known as the Schultz-Charlton phenomenon. This consists in the fact that the serum of a convalescent from scarlet fever will, when injected into the skin of a patient showing the rash, produce local bleaching of the scarlet fever rash. This is a specific property of the serum and one not present in normal human serum or in the serum of animals; the reaction is also specific for the scarlet fever rash, being absent with similar eruptions not due to this infection. Work at present under way, both in this country and in America, tends to show that a like effect is produced by the serum of animals which have received immunising injections of the scarlet fever streptococcus.

The whole of the investigations we have been reviewing are as yet in the experimental stage, and much needs to be done before their worth can be finally judged. Such evidence as has been produced, however, goes to focus attention upon the possibility of the streptococcus being the actual ætiological agent of this disease. With the wider application of these tests it will be interesting to learn the results obtained in puerperal scarlet fever and in those cases of wound infection which simulate this disease; while greater knowledge of the bacteriology of this section of the streptococcus group must result in fresh attempts at serum therapy. Such attempts are indeed already being made. It is noted by Okell and Parish that antitoxic serum, prepared in the institute to which they are attached, produces the Schultz-Charlton phenomenon and therefore has some properties in common with the serum of convalescents. In America also the matter is being closely investigated and, as noted in the *Journal of the American Medical Association* of March 14th, two types of anti-serum are in the field. The one, an antistreptococcal serum proper, has been produced by Dochez and Blake; this differs only from the previously tried and abandoned antisera, which date back to Marmorek's work, in its being prepared from serum-typed scarlatinal strains of the organisms and in a rather special technique of preparation. The other is an antitoxic serum, more comparable to diphtheria antitoxin, which has been prepared by injecting horses with the Dick toxin; this serum, as Henry and his collaborators show, may probably be prepared in concentrated solutions. It is possible that a combination of these sera may be more potent than either of the two utilised singly.

THE IRISH FREE STATE AND THE MEDICAL AND DENTISTS ACTS.

The question of the position of the Irish Free State in connexion with the Medical and Dentists Acts of the United Kingdom first arose in January, 1922, when the Secretary to the Provisional Government of Ireland Committee wrote a letter to the Ministry of Health, in which it was set forth that constitutionally the position would be that the arrangements then in force would continue unaltered unless, and until, the Parliament of the Irish Free State or Northern Ireland saw fit to legislate for practitioners within their respective areas. It was within their power to pass such legislation, and, if so, consequential legislation by the British Parliament might be necessary. A reply was sent that the repeal or alteration of the parts of the Medical and Dentists Acts concerned would be very difficult without dislocating the machinery of the Acts as regards the registration of practitioners holding Irish qualifications; as regards the constitution of the General Medical Council; and as regards finance. It was suggested that it was perhaps unnecessary to take any legislative steps at that time, the best plan being to wait and see whether separate Irish legislation was proposed.

In March, 1924, attention was drawn to the Irish Free State (Consequential Adaptation of Enactments) Order, 1923, wherein it was provided that references in any enactment passed before the establishment of the Irish Free State to the United Kingdom, should, in the application of the enactment to any part of Great Britain and Ireland other than the Irish Free State, be construed as exclusive of the Irish Free State, except as regards certain Acts mentioned in the schedule. In the schedule, however, the Medical and Dentists Acts were not specifically mentioned. The question therefore arose whether these Acts thereby ceased to apply to the Free State. The matter became acute at this time, because the election of the Dental Board was pending and it was essential that the question with regard to its constitution should be cleared up. The question would also arise in connexion with the election of Direct Representatives of the Council by medical practitioners resident in the United Kingdom, which was to take place later in the same year. It seemed to be quite clear that, under the Order above referred to, it was no longer necessary for dentists in the Irish Free State to retain their names on the Dentists Register of the United Kingdom, unless they wished to practise in Great Britain or Northern Ireland, but beyond this the matter was still somewhat obscure. A legal opinion was obtained from counsel of eminence that the electorate for the Dental Board was confined to dentists practising in Northern Ireland, and that the member of the General Medical Council appointed to represent the Council on the Dental Board must be a member from Northern Ireland. The position in regard to dentists therefore appeared to be practically decided, but the question of the application of the Medical Acts, which was the more important, still remained to be settled. An important meeting of those concerned took place at the Privy Council Office in July, 1924, at which the terms of a Bill to be introduced into the Saorstát were agreed upon; and it was then understood that legislation would be introduced into the Irish Free State Parliament immediately and be followed by a short enactment in the United Kingdom to put the question of interim registration in order. Unavoidable delay, however, occurred, and the Free State Government asked that the *status quo* might be preserved until the problem had been legally solved. This was agreed to on behalf of the Council; but it was not until the beginning of the current year that a new Act was passed by the Parliament of the Irish Free State and received the Royal Assent on Feb. 21st, 1925. The Act (Saorstát Eireann—No. 2 of 1925) authorises the General Council established by the Medical Acts to continue temporarily to exercise jurisdiction and authority under those Acts in respect of medical practitioners in Saorstát Eireann. Legislation is about to be introduced into the British Parliament which will have the effect of completely removing the remaining difficulties. It will be noted that the Southern Ireland Act continues in force for one year. Unless there is a change of policy in the Irish Free State, it is reasonable to hope that it may be continued under an Expiring Laws Continuance Act.

To sum up, the position now is as follows:—The Medical Acts of the United Kingdom have effect in Southern Ireland as they had before the establishment of the Free State; Irish qualifications continue to be registrable on the British list; and the Irish Universities and Corporations continue to be represented upon the General Medical Council, which still continues to have the jurisdiction throughout Ireland which it possessed before the formation of the Irish Free State. With regard to dentists, as the Dentists Acts do *not* now apply as before to the Free State, qualifications obtained will be registrable only individually, and on their respective merits, as in the case of British possessions like Canada or Australia. Dentists in the Free State, already registered under the Acts of 1878, 1921, and 1923, whose names are still on the Dentists Register, may continue to have them published therein on fulfilment of the prescribed conditions. All registered practitioners, wherever resident, continue to be *ipso facto* under the disciplinary jurisdiction of the Dental Board and the General Medical Council. There is, however, no special Dentists Act at present operative in the Free State. It has been stated that separate legislation for the control of the practice of dentistry is contemplated by the Free State authorities, but meanwhile no regulations for the control of the dental profession have been issued.

ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.—The twenty-fourth meeting of this Commission was held at the Home Office, Whitehall, on April 2nd, Sir Andrew Duncan in the chair. Evidence was given on behalf of the National Federation of Employees' Approved Societies by Mr. Henry Lesser, President of the Federation. Sir Thomas M. Legge, of the Home Office, senior medical inspector of factories, gave evidence on the medical work in factories and workshops, and suggested possibilities of development in that work. Mr. V. L. Bilbey, the clerk in charge of the Ministry of Health inquiry room, was examined as to the volume and nature of the inquiries and complaints made by employers and insured persons. The Commission announce that proof copies of the oral evidence and the relative statements submitted at the meeting, March 19th, are now on sale at H.M. Stationery Office (4*s.* 6*d.*).

Annotations.

"Ne quid nimis."

SPECTACLES AND CANCER.

THE experimental demonstration that cancer can be produced by chronic irritation renders of special interest every clinical observation on man in which a similar relationship between chronic irritation and the onset of cancer can be demonstrated. A number of cases have been reported from America during the last few years[1] [2] [3] in which injury due to the wearing of badly fitting spectacles has been made responsible for the onset of cancer. Altogether 13 such cases have been recorded. In most of these the site was the bridge of the nose. In a paper entitled the Menace of Poorly Fitted Spectacles in Old Persons, Dr. J. J. Morton[4] recently reported four such cases which have come under his notice within the short space of three years. One of the patients was 50 years of age, the other three well over 60. The sites of the tumour were either the temple, where the bow of the glasses rubbed, or in one case behind the ear. One of the tumours, which had been noticed for two years, was a cutaneous horn; the other three were diagnosed on microscopic section as basal cell carcinomata. The tumours were treated with radium, apparently with success. It is interesting to note that in these cases the form of chronic irritation was mechanical. Another interesting point in the history of these cases is that a lesion of the skin at the site where the tumour developed later had been noticed by one of the patients 12 years, by another patient 20 years, before the cases came under Dr. Morton's notice. The period of chronic irritation must therefore necessarily have been longer. It is a significant fact that the very different forms of chronic irritation, such as tar cancer, aniline cancer, and the mechanical irritation of these cases, require a prolonged period, extending over very nearly the same length of time—about 15–25 years. Under very exceptional conditions this period may be shortened, as instanced by the cases quoted by Dr. Marshall Findlay in THE LANCET of April 4th, perhaps because the intensity of the irritation and the site to which it was applied were particularly favourable. It seems likely that, as Dr. Morton suggests, such cases of cancer due to badly fitting spectacles are not infrequent in old people, but have not been recorded in the literature.

THE EFFECT OF WINE ON PULMONARY TUBERCULOSIS.

Professor Arturo Campani, director of the Red Cross Sanatorium at Cuasso al Monte, publishes[5] the results of his investigations on the 406 patients there with a view to determine the influence of alcohol in inducing or aggravating pulmonary tuberculosis. These patients were all males of the age between 20 and 47, mainly war pensioners, and may be divided into four groups, heavy, ordinary, and moderate drinkers and abstainers. For statistical purposes Prof. Campani took three groups: (1) All the patients en bloc to establish an average; (2) heavy drinkers; and (3) abstainers. Each case was investigated with regard to age, variations of weight, stage of the lesion, occurrence of hæmoptysis and fever, and presence or absence of Koch's bacillus. Without giving actual figures, it was found that the average age was greater in those who used alcohol in the form of wine, the weight was slightly greater in the drinkers than in the abstainers, the prevalence of right-sided lesions also greater in the former, while in the latter bilateral lesions had a percentage more than double. Fever and the presence of Koch's bacillus were more marked in abstainers. As to the percentage of improvement under sanatorium treatment, including the so-called cures, the general average was 60·5 per cent., with 76 per cent. in drinkers and 55 per cent. in abstainers, while the mean mortality of 1·9 per cent. was divided between 0·6 per cent. in drinkers and 3·1 per cent. in abstainers; on the other hand, there was a slightly increased prevalence of hæmoptysis among the drinkers, 66 per cent. as against 62 per cent. in the abstainers, but the prevalence of acute forms, or acute forms occurring in the course of chronic, was 0 per cent. in the drinkers and 8·1 per cent. in the abstainers, the average being 3·2 per cent. In face of these figures, says Prof. Campani, it is difficult to resist the desire to affirm that wine is far from being a poison predisposing to tuberculosis, but rather constitutes a means of defence against the invasion of the disease. He admits that statistics are often deceitful, but considers that the assertion that alcoholism generates tuberculosis should be subjected to severe and serious criticism for the reason that it is contrary to a well-known anatomical truth—namely, that alcohol directly or indirectly favours the formation of connective tissue, that it is a cirrhotic and sclerogenic poison par excellence. It is known that tuberculosis does not fall into line where there is a tendency to sclerosis; it is rare in the early stages of cirrhosis either of the kidneys or liver or heart and lights up only as a terminal cachectic factor. It is difficult to imagine that a fibrogenic substance, a producer of the very tissue which is the sole barrier to the extension of tuberculosis, should be harmful in the clinical picture of the disease, or that such a wasting disease should militate against an aliment which is recognised as having a saving function in organic metabolism. Prof. Campani concludes by stating as his opinion that neither general statistics nor clinical observation have strengthened the generally widespread idea that alcohol, at least in our temperate climates, and especially in the form of wine, is a harmful agent in pulmonary tuberculosis, but that his present observations, although not of large extent, seem to prove the contrary.

SOME CURIOUS OBSERVATIONS ON THE TEETH.

A verbatim reprint[1] of the first known work on dentistry in the English language has just been published. It has a second claim to interest, possibly of greater value in the sale-room, in being one of the few examples of printing in Dublin in the seventeenth century. Although the title of the book has been given in various dental bibliographies during the nineteenth century, nothing was known of its contents until Mrs. Lindsay, L.D.S., whose skill and enthusiasm as a dental bibliographer is well known, unearthed a copy from the British Museum. In a scholarly introduction she has gathered together such information as is available about the book and the author. The book first appeared as part of a larger medical treatise in 1686. In the following year it was printed separately under the title given above and with the author's name. Of this edition only eight copies are known. By a curious chance, soon after Mrs. Lindsay had discovered the copy in the British Museum but before she had published an account of it, Dr. Weinburger, of New York, found a copy among a collection of books which had come from this country and described it in an American dental journal. Of Charles Allen nothing is known; evidently he was in practice in Dublin. In publishing this book he appears to have been influenced by the possible increase in his practice rather than by a love of science. Thus in a chapter on the alteration of the teeth with their remedies, he refers to a dentifrice which he has compounded. With a delightful ingenuousness he ends his pamphlet thus: "But I shall always deal candidly with everybody, never undertaking anything but what I shall be able to do according to agreement, and if anyone will be pleased to come to my chamber he may have my advice (concerning anything that belongs to my profession) gratis at any time." There is shrewd sense in much of what Allen says and some of his statements are quite startling in their modernity. His account of the pathology of pulpitis, for instance, is substantially accurate. In discussing the "restauration of the teeth," Allen speaks of the operation of implantation which he considers inhumane and only "robbing Peter to pay Paul." He suggests as an alternative the possibility of replacing a carious tooth by one taken from an animal, such as a dog, sheep, goat, or baboon. There is nothing to suggest that he ever practised this method and evidently it is a by-product of an ingenious imagination. It was a happy thought on the part of Mrs. Lindsay to reprint so quaint a pamphlet, for it has an historic interest as representing the commencement of dental literature in our language.

GAS CYSTS OF THE INTESTINE.

Gas cysts have been known for a long time to occur in the intestines of certain animals, and John Hunter described this condition in the case of the pig. The first undoubted case of this rare disease in man was described by Bang in 1876, and recently H. W. Mills has collected 97 published cases and added three of his own to bring the total to 100.[1] These gas cysts of the intestine may be discrete or confluent, sometimes occurring in masses large enough to cause mechanical obstruction, and occasionally a single large cyst may occur instead of multiple small ones. The cysts are frequently pedunculated and so extremely like hydatid cysts of the peritoneal surface of the intestine that they can often only be differentiated by a microscopical examination. They may occur over a few inches or along the whole course of the intestine. A diagnosis is usually made during an operation for intestinal obstruction or at a post-mortem examination, when putrefactive changes may apparently give rise to similar but not identical cysts. The disease is benign in itself and tends to spontaneous cure, but it may cause complications by its mechanical effects. Excision of the affected part of the gut may be necessary if such mechanical obstruction has occurred, and, on the other hand, if at operation some mechanical cause for the condition of gas cysts be found, this must be dealt with. For it appears that the mechanical theory of the origin of these cysts is most widely supported. Mills says that the question of ætiology is still *sub judice*, and he describes the theories advanced under four headings. According to some authorities these cysts are formed by an invasion of the wall of the intestine by a gas-producing bacillus of the coliform group or by some attenuated anaerobic organism. Such anaerobic bacteria appear to have been isolated in one case, but in the large majority the contents of the cyst are sterile. A chemical theory has been advanced, without much evidence, and a neoplastic theory which looks upon the whole condition as a new growth, the cells of which secrete gas. The theory which obtains most support, however, is that which looks upon these gas cysts as being formed mechanically. Although the cause is not always the same, it seems that obstruction somewhere in the gastro-intestinal tract is commonly present and a stenosis of the pylorus following ulcer in this situation has existed in a very large number of reported cases; according to one author in as many as 72 per cent. This mechanical theory states that the action of a distended stomach drives gas along the base of an ulcer under the peritoneal coat and intestinal peristalsis helps to pass the gas along. In one case a constriction, with some ulceration, occurred in the ascending colon. Above this gas cysts appeared, their presence being limited to this portion of the bowel by a sharp angle at the hepatic flexure. In some cases acute infection seems to play an additional part in the production of gas cysts, and they may then contain gas from the intestine plus that produced *in loco* from a secondary infection of some traumatic lesion in the intestinal mucosa. The nature of the gas in these cysts is still unknown: it is apparently odourless and non-inflammable. Oxygen is always present, thereby, according to some authorities, excluding the possibility of a bacterial origin when hydrogen and carbon dioxide would be expected without any oxygen. The cases collected in this paper come from all over the world, so the condition, rare as it is, appears to be universally recognised. In this country Nitch and Shattock gave an account of two cases and discussed the ætiology before the Royal Society of Medicine in 1919.

FATTY CONTENTS OF THE OVUM.

At a recent meeting of the Anatomical Society at King's College, London, Prof. Arthur Robinson gave an interesting and novel account of the non-saturated fats present in certain mammalian ova. The photographs which were thrown on the screen showed very strikingly the variations in the fat content in different sorts of eggs, the ferret, for example, being heavily loaded with the substance, while the human ovum contains apparently none of it at all. It is well known that the indefinite class of "lipoids" seems to form a kind of stable or permanent basis in cell-morphology, but these observations made by Prof. Robinson do not seem to apply to quite the same thing. That these fatty substances affect the morphological structure is apparent nevertheless, for the protoplasmic contents of the cell can be present only between and among their minute droplets. The observations are an important addition to the data available on an obscure and little known subject, and provide many new problems connected with the changes observed in the location of the fatty matter during the processes of further development. Prof. Robinson also drew attention to the fact that there seems to be no evidence at all of the path or means by which the non-saturated fat finds its way into the ovum, for there is absolutely no sign of its existence at any time in the cells or fluid surrounding the germ-cell in the follicle.

A DISEASE PECULIAR TO BREAST-FED INFANTS.

Japanese physicians have been aware for some years of the existence of a disease which occurs only in breast-fed infants, and which produces in them a profound disturbance of the central nervous system. There is still some divergence of opinion as to the existence of some relation between this disease and the presence of beri-beri in the mother. Dr. T. Tanaka has written an interesting account of this ailment,[1] illustrated by the clinical notes of eight cases which he observed. A prodromal dyspeptic stage, with vomiting or diarrhœa, is followed by the appearance of general cerebral symptoms such as irritability, insomnia, and drowsiness. If the child is taken from the breast at this stage rapid recovery of health takes place. If breast-feeding is continued, it is usual to find focal signs of cerebral involvement after a few days. Ptosis and upward rotation of the eyeball are the first of these to appear, and are followed later by crossed paralysis, incoördination and muscular asynergy, or some form of hyperkinesis, and occasionally by convulsions. Weaning the child is almost always followed by rapid recovery from the acute phase of the disease, with residual spastic paralyses which tend to improve more slowly. Of the author's cases only one was fatal; unfortunately there was no autopsy, and little light seems to have been thrown on the morbid anatomy by the other authors cited. Dr. Tanaka reviews critically the question of the distribution of the cerebral lesions. From the clinical signs described they are obviously extensive and appear to be multiple. Lesions of the pons, mid-brain, and basal ganglia must all have been present, sometimes in the same case. Dr. Tanaka was impressed by the resemblance which the physical signs and clinical course of these cases bear to those of Wernicke's cases of polio-encephalitis hæmorrhagica superior, and he has reproduced the account of two of these for comparison; he believes this disease to be of a similar pathological nature. The resemblance is certainly very close, and verification of Dr. Tanaka's hypothesis by a study of the morbid histology when opportunity presents itself may be awaited with interest. The author is of the opinion that the disease is not connected with maternal beri-beri; apart from this point, he has made little reference to the problem of the exact causal factor present in human milk.

THE EPIDEMIOLOGY OF SLEEPING SICKNESS.

Dr. G. D. Hale Carpenter, who is well known for his researches on the tsetse-flies of Central Africa, and who is the author of a particularly charming book entitled "A Naturalist on Lake Victoria," has been engaged on an investigation into the epidemiology of sleeping sickness in Central Kavirondo, Kenya Colony. The policy adopted by Kenya, during the epidemic of sleeping sickness which raged round the lake at the end of the last century, differed materially from that of Uganda; the Kavirondo people were not forcibly removed from the lake shore, whereas in Uganda wholesale depopulation of all islands and of the mainland within two miles of the water was enforced. The results which one would be led to expect as the outcome of these measures would be a natural re-distribution of the population, certain parts being avoided as too dangerous for habitation, while the inhabitants of others would be liable to suffer from outbreaks of the disease. The researches of Dr. Carpenter were undertaken as the result of the suggestion of Mr. W. F. Fiske, formerly medical entomologist in Uganda, that the number of male *Glossina palpalis* caught by one fly-boy per hour might constitute a standard of safety. The limit for a population of over 30 per square mile, living in contact with the fly along the coast, would be ten males caught per hour. This suggestion was confirmed by the investigations. Only four localities were discovered where trypanosomiasis now exists, and in these areas there was a population of density of over 40 per square mile, and *Glossina palpalis* was caught at the rate of more than 15 males per boy per hour. The epidemic of sleeping sickness in Central Kavirondo was introduced about 22 years ago. Mageta Island was evacuated, but the subsequent return of the population caused a recrudescence of the disease which led to a second evacuation, a second return and a renewal of sleeping sickness in 1920–21, which led to a final evacuation in 1922. The tsetse-fly—*Glossina palpalis*—occurs plentifully along the 100 miles of coastline examined between the Siò River and the mouth of the Kavirondo Gulf; ample evidence was obtained that the chief food-supply in this area consists of non-mammalian blood. *Glossina brevipalpis*, on the other hand, occurs in the dense bush where hippos sleep, and much prefers their blood to any other. It was found that stretches of country behind dense belts of papyrus are free from tsetse-flies, and it is suggested that the population should be encouraged to return to those parts in preference to others. In other areas the general population may be rendered reasonably safe by clearing all landing and watering places for 200 yards along the coast on each side of the actual landing or 50 yards back from the water. It was found impracticable to examine the lake shore population systematically, nor was it considered expedient to establish the diagnosis by gland puncture, but reliance was placed upon palpation of the cervical and axillary glands. No advanced cases of the disease were seen, and the majority of those diagnosed as trypanosomiasis seemed to be in good health. The presence of these infected people in a settlement on the mainland in close contact with Jaluo natives, of whom none so far have acquired the disease, is certainly strong evidence that the glossina is the chief agent in its dissemination.

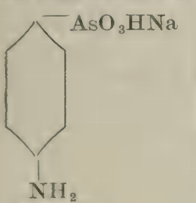
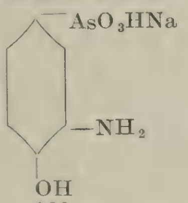
STOVARSOL.

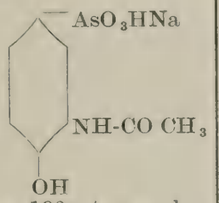
THE first three months of the present year have seen what might be termed a revival of discussions upon therapy in syphilis. The various medical journals of European countries and America have published original papers, comments, and discussions on both the classical forms of treatment, and also on some new methods. Whereas the English and American publications deal almost exclusively with such problems as the merits of bismuth in the treatment of syphilis, French and German papers refer in addition to a comparatively new remedy, stovarsol, or 190. The history is as follows. In 1922 C. Levaditi and A. Navarro-Martin[1] began to study the spirillicidal action of bodies related to atoxyl and prepared by Fourneau. One of the first of their series was amino-oxy-phenyl arsenite of sodium, or 189. Although this substance possesses marked therapeutic properties, the ratio of the tolerated dose to the curative dose was low, and the investigators prepared a further series of derivatives on similar lines. They found that the acetyl derivative of 189 possessed much greater curative powers, and the toxic properties were much reduced. The relation of the three bodies, atoxyl, 189, and the acetyl derivative, 190, or stovarsol, can readily be seen from the following formulæ:—



Atoxyl.



189.



190, stovarsol.

One of the most remarkable properties of stovarsol is that it can be readily absorbed from the alimentary canal. All the curative experiments of Levaditi and Navarro-Martin were conducted by oral administration of the remedy. The first test of stovarsol was to try its curative powers upon the various spirochætal infections in rabbits, and since it was proved to be very potent, the investigators applied it to human syphilis. In collaboration with A. Marie, Levaditi and Navarro-Martin performed a very interesting experiment. A volunteer was scarified on both arms and a "virus dermotrope" was rubbed in. At the same time a monkey was inoculated with the same virus. Two and a half hours later 2 g. of stovarsol were given to the human subject by mouth, and the dose was repeated 16 hours later. Whereas the monkey developed typical syphilitic lesions, the volunteer rested immune from any symptoms, and his Wassermann reaction remained negative throughout. This experiment suggested that stovarsol might be used as a prophylactic. In collaboration with other workers [2 3] it was demonstrated that this drug, taken by the mouth, was able to protect against syphilis. These clinical experiments, of which detailed protocols have been published, were conducted with great care and thoroughness. Thus it was shown that the wives of syphilitics with primary lesions, although fully exposed to infection, could be protected by the oral administration of stovarsol alone. 2 to 4 g. may be given with safety, and the investigators claim that in stovarsol lie the properties of the ideal prophylactic substances. Its value apart from syphilis has been pointed out by many workers. Thus E. Marchaux[4] described its use in lamblia infections and in amœbic dysentery. C. Baermann[5] described cures effected by it in cases of frambœsia. Levaditi summarised the views of his school upon the prophylaxis of syphilis in an address to a conference at the Institut Pasteur in April, 1923, where he said: "J'estime qu'en pratique, lorsqu'il s'agira d'un sujet ayant eu des rapports suspects, une cure de deux à trois grammes de stovarsol, commencée dès le lendemain, à jeun suffiront. En cas de contagion certaine ou très probable (rapports répétés avec un syphilitique à manifestations ouvertes), il y aura lieu de suivre une cure de 4 à 5 grammes à raison d'un gramme par jour (4 comprimés)."

During the last few weeks two papers upon this question have appeared. M. Petzetakis[6] deals with the use of the drug in amœbic dysentery. His conclusions are instructive. He found that in doses of 0·5 to 1·0 g. by mouth, stovarsol was of the greatest use in the treatment of amœbic dysentery. In the acute stages the remedy could be given with complete safety, and very beneficial results were obtained, as evidenced by a decrease in the number of stools and a diminution of pain, and other clinical manifestations of the conditions. From an extensive examination of the fæces this observer concluded that the drug possessed "propriétés amœbicides incontestables." Resistant or chronic cases responded particularly well; and in cases intolerant to emetine and in infants it is regarded by the author as invaluable. He also recommends its use as a prophylactic. These observations of Petzetakis thus supplant the work of Marchaux already quoted. Weiner Worms[7] considers the drug from an experimental point of view. His results of the curative effects of stovarsol upon spirochætal infections in rabbits are not in strict agreement with those of the original investigators. His results are summarised in a series of tables, and the word "nichtgeheilt" is applied frequently to rabbits infected with the *Spirochæta cuniculi*. That the drug possesses marked protective powers Weiner Worms does not deny, but he implies that in order to get complete protection, there is a danger of pushing the drug to toxic limits.

It could hardly be expected that the new remedy would prove to be entirely free from the disadvantage which limited the practical value of its predecessors, the difficulty of finding a dosage adequate for the destruction of the invading organism and yet not toxic to the tissues of the host. However that may be, the convenience of oral administration is so great that the profession will welcome the introduction of this compound. If the results hitherto obtained are substantiated in wider fields there can be no doubt that the drug is a remarkable advance on former products.

THE BRITISH SPA FEDERATION.

AT the annual meeting of this Federation, representing Bath, Buxton, Cheltenham, Droitwich, Harrogate, Leamington, Llandrindod Wells, Woodhall Spa, Strathpeffer and the New Zealand Government Spas, which has just been held in London, the conditions of membership, with which every spa admitted to the Federation must comply, were formulated and adopted. Under these principles of standardisation a spa, to be recognised by the Federation, must possess natural mineral waters of known therapeutic value; an approved bathing or pump-room establishment, to be in the hands of a public body or an approved private body; a local medical authority suitably equipped in the specialty; and proper hotel accommodation, with approved amenities and sanitary conditions. Further, the Federation enjoins that treatments can be given only under medical prescription not more than

[7] Deutsch. Med. Woch., Numm. 11, 428, 1925.

12 months old, except in the case of certain minor treatments definitely specified by the local authority. Before the admission of any spa to the Federation, three representatives of that body (one being a spa medical practitioner) will visit and report along the lines thus indicated, the Federation in this way emphasising the necessity of a high standard of practice at the British spas and of coöperation between its members and the medical profession. It is the aim of the federated British spas by these and other means, combined with the research work which is now going on at several spas, to provide medical men with hydrological centres in this country, at which they may be sure of their patients receiving efficiently administered treatment.

The hon. secretaryship of the Federation is to be held in turn by representatives of the various spas, and Mr. John Hatton, the director of the baths of Bath, was elected to that office in succession to Mr. F. J. C. Broome, general manager of the Royal Baths, Harrogate, who received the warm thanks of the Federation for the valuable service he has rendered.

THE ENERGY UTILISATION IN EMOTIVE EXPRESSION.

Some experiments have recently been carried out by Dr. Hermann V. Schroetter, of Vienna,[1] in which the energy usages in expression have been compared with those of ordinary speech. The experiments were made on a well-known elocutionist, who for purposes of control remained at rest, or read, as in a lecture, without emotional expression. The results so obtained were compared with those obtained in laughing, crying, or sobbing. In the ordinary reading it was found that about 20 L. of air were breathed per minute, while the energy expenditure deduced from the respiration data showed an increase of 85 cal. per hour above the resting value. For laughing and sobbing the volumes breathed were 22 and 12 L. per minute respectively, while the increase above the resting value was 12 and 5·5 cal. respectively. The actual work involved in speech amounted to 9250 kilogram-metres per hour, that in laughter 1300 kgm., and that in sobbing only 580 kmg. per hour. Sobbing is thus, from the physiological standpoint, a cheap form of entertainment. Each spoken syllable is calculated to cost about 0·5 kgm. The loss of moisture by the lungs is about the same in speech as in laughter—viz., about 42 g. per hour—while sobbing only accounts for a loss of about 18 g. per hour. Dr. Schroetter's experiments are of a thoroughly interesting character.

PHYSIOTHERAPY IN HEART DISEASE.

During and after the war graduated exercise proved to be the mainstay in the treatment of soldiers suffering from D.A.H.; yet, as Dr. G. H. Hunt rightly says in the first of a series of articles [2] dealing with massage and remedial exercises in medicine, writers on this subject have devoted but little attention to the fundamental principles which underlie the use of these measures in the treatment of organic heart disease. This appears to be due principally to lack of coöperation between the physician and the masseur, the former having been not unnaturally prejudiced against the use of massage on account of certain practices based on fundamentally unsound doctrines which still find a place in some of the text-books on the subject. The so-called "local heart treatment" is a case in point. It is totally valueless in organic disease; and, by directing the patient's attention to the heart, it is positively harmful in the purely functional disorders. In the acute stages of heart disease, whether one is dealing with an active infection or with acute myocardial insufficiency supervening in the course of chronic disease, where the heart is already the seat of an old-established lesion, the supreme importance of absolute and complete rest has long been recognised. During the stage of convalescence, however, the institution of massage and breathing exercises is of value in aiding the venous return to the heart and in promoting the nutrition of the tissues, whereas the gradual addition of passive and active movements forms a suitable preparation for the somewhat sudden change to which a patient is subjected when he is allowed to get up for the first time. The increase in pulse-rate produced by standardised "test exercises" affords a simple and reliable means of graduating the duration and extent of the treatment at any particular stage of the illness, and serves to indicate the progress which is being made. At the present day various functional tests of the exercise tolerance have been so universally adopted, in supplementing the mere physical examination in cases of heart disease, that it is rather surprising that more attention has not hitherto been paid to the use of physiotherapy in this particular department of medicine.

PROFESSOR WARDROP GRIFFITH.

Dr. T. Wardrop Griffith has placed before the Council of the University of Leeds his resignation of the Professorship of Medicine. In a letter to the Council he has pointed out that in harmony with the rules of the General Infirmary at Leeds he becomes a member of the consulting staff next September, by which time he will have served for twenty years on the full staff. It is this fact which has led him to anticipate the age-limit for the tenure of office which attaches to professorships in the University; for although, as is happily the case in Leeds, members of the consulting staff have the privilege of admitting a limited number of patients to be under their care in the infirmary and continue to work within its walls, he felt that the best interests of the University would be served if he did not retain the professorship after he had retired from the full staff and the regular routine teaching which that involved.

The resolution passed by the Council of the University of Leeds in response to Dr. Wardrop Griffith's letter was as follows:—

> The Council accepts the resignation of the senior professor—Prof. T. Wardrop Griffith, with deep regret. He was appointed to the Chair of Anatomy in 1887 and transferred to the Chair of Medicine in 1910, a continuous record of 38 years. He began work in the old Medical School in Park-street and took an active share in the construction of the new school in Thoresby-place, in which he established one of the best anatomical departments in the Kingdom, filling it with many valuable collections, and in one cardiac section a unique collection of specimens prepared by his own hands. His assiduous attention rendered his tenure of office of the Chair of Anatomy little different from a full-time office, as every hour spared from hospital work and consulting practice was spent with energy in the department, and there is no department of its kind more entirely the creation of one man's zeal and love. In his tenure of the Chair of Medicine he has added to the lustre of its history by the high quality of his observations in clinical fields and able exposition of his subject, attaining an eminence acknowledged by his admission to the Order of St. Michael and St. George and the conferment of the honorary doctorate of Laws by his own University of Aberdeen. In both departments his courses of lectures have been noted for their vivid quality and the perfection of arrangement and delivery. In the Faculty and University he has played an important part by sound advice and an example of devotion for which a heavy debt of gratitude and affection is due. His resignation marks the completion of one of the soundest pillars on which the school has been reared, and the Council, looking forward to the support which will remain in his work and the effects of his work, desires to record its appreciation of his most valuable and enthusiastic services, its grateful thanks for the distinction he has brought to the University, and its cordial hope that he will, for many years to come, enjoy the ability to pursue the practice of his profession and add to the many contributions by which he has advanced the cause of medicine.

From this resolution, upon whose accuracy we congratulate Dr. Wardrop Griffith, it will be gathered that resignation of the official position is not accompanied by withdrawal from practice.

ELIMINATION OF THE TUBERCULOUS COW.

ON several occasions recently both medical and veterinary societies have passed and submitted to various Government bodies resolutions in favour of the return to the statute book of the Tuberculosis of Animals Order, 1914, or to some up-to-date modification of it. Hence a paper on the elimination of the tuberculous cow, which was read by Mr. Thomas Parker, F.R.C.V.S., chief veterinary inspector for Newcastle-on-Tyne, before the congress meeting of the Royal Sanitary Institute in January last, is of particular interest. The paper is published in full in a recent issue of the *Veterinary Journal*, and Mr. Parker deals with the subject from the practical aspect of the veterinary inspector. He gives a number of sound reasons why immediate action should be taken and why our present method fails in preventing continued infection from tuberculous milk. The system of protection, as now in force, fails, he holds, (1) because not only the milk, of which the sample formed part, but also the daily supply from the same source, will have been consumed, probably in most instances for weeks, before the sample has been proved tuberculous or otherwise; and (2) because, although the sample has been proved tuberculous, the animal producing it may, in the meantime, be removed to some other herd and lost sight of. It seems ridiculous that a cow which has been proved by the tuberculin test, applied by a qualified veterinary surgeon, to be a disseminator of tubercle bacilli in her milk should not be put out of the reach of further harm by compulsory destruction; yet by the present method such an animal is merely removed from the herd and may be there is nothing to prevent her being sold to a dairy farmer in another district where inspection is not so strict. As Mr. Parker says, "It is absolutely essential, in any attempt to secure a wholesome milk-supply, to have all clinically tuberculous cattle removed from dairy herds, and this cannot possibly be done without regular veterinary inspection of all dairy herds throughout the country." He concludes his article by stating "that it should never be forgotten that the results we all desire will be attainable only in the inverse ratio as to the completeness and regularity of inspection and the promptness with which the disease is dealt with at its source. In no other way can we hope to arrive at a stage of affairs when it can honestly be said that we are attempting to eliminate the offending cow and thus prevent one of the completest and valuable of all foods being charged with the germs of a dangerous disease."

THE FACTORIES BILL.

LAST week, after we had gone to press, the Cabinet arranged that the Factories Bill should be proceeded with this session, a decision with which the medical profession will be in full accord. There is general anxiety in the House that the Bill should be presented in a form which would lead to its passage through Parliament with the united support of all parties, and it will probably be presented shortly after Easter.

IN accordance with general anticipation, and with no serious opposition whatever, Sir Humphry Rolleston, Regius Professor of Physic in the University of Cambridge, was re-elected on Monday President of the Royal College of Physicians of London.

PARIS: DERMATOLOGY AND VENEREOLOGY.—A post-graduate course at the Faculty of Medicine of Paris in dermatology, with lectures and demonstrations, will be held from April 22nd to May 25th, at the Hôpital St. Louis, and a course in venereology will follow at the same hospital from May 27th to June 24th. The courses are under the direction of Prof. Jeanselme, assisted by many distinguished colleagues. Further particulars may be obtained from Mr. Burnier, Hôpital St. Louis (pavillon Bazin), 40, Rue Bechat, Paris (X.).

Modern Technique in Treatment.

A Series of Special Articles contributed by invitation on the Treatment of Medical and Surgical Conditions.

CXVII.—THE TREATMENT OF LACRYMAL OBSTRUCTION.

OBSTRUCTION of the lacrymal passages leads to a troublesome epiphora for which the patient, usually after putting up with discomfort for weeks or months, finally seeks advice. The importance of treatment lies in the fact that these cases practically never recover spontaneously and that the presence of a chronically inflamed lacrymal apparatus is a constant serious menace to its possessor. It has been shown bacteriologically that the thickened atonic lacrymal sac in these cases acts as a culture-tube and reservoir for a varied assortment of virulent micro-organisms. The most important of these, and one which is very frequently present, is the pneumococcus, and when it is realised that this organism can in the presence of the least abrasion of the corneal epithelium give rise to a serious hypopyon ulcer, and even lead to panophthalmitis and loss of the eye, it is obvious that no case of chronic lacrymal obstruction should go untreated.

The first step in the treatment is the recognition of the type of obstruction, and here a consideration of the history, the age of the patient, and the coexistence of nasal or other disease is of assistance.

One may roughly group the cases into three groups, the first being the commonest, the second less common, and the third very rare. 1. The patient is an adult usually past middle age. There is a slight swelling at the site of the sac, and pressure on this causes regurgitation of pus or mucus into the eye. The obstruction is somewhere in the nasal duct. 2. The patient is an infant and the obstruction was noticed soon after birth. There is regurgitation on pressure over the sac. In these cases the nasal duct, which develops as a solid rod of epithelial cells, has failed to canalise and has remained blocked by shed epithelium. 3. The patient is usually young or very old. There is *no* regurgitation on pressure over the sac, and on inspection an abnormality of the punctum can be seen. In the young this may be a congenital displacement, excessive smallness or complete atresia; in the aged it is displacement forwards due to the laxity of the lid (senile ectropion). Blocking of the punctum by a scar, a foreign body, or a concretion may, of course, occur at any age.

The treatment in all cases should be in the first place conservative, operative measures being resorted to only when this fails.

Adults with Obstruction in the Nasal Duct.

In the first group the treatment can be considered under three headings: (*a*) Re-establishment of the natural passages. (*b*) Extirpation of the affected sac. (*c*) Establishment of a new passage. The nose should be carefully inspected at the outset, since it is obvious that treatment directed towards the cleansing of the inflamed sac will be of little avail if the lower end of the nasal duct is blocked by a polyp, a hypertrophied turbinate, or a misplaced septum. If any intranasal cause is seen this should be dealt with at once.

The infected sac may then be treated as follows: After cocainising the conjunctiva the lower punctum is dilated with a Nettleship's dilator so that it will admit the nozzle of the lacrymal syringe. It is never necessary to slit up the canaliculus at this stage, and, indeed, this should not be done at all unless absolutely unavoidable, since, although a large opening is thereby made into the sac, the capillary action of the small duct is lost and the epiphora may continue from this cause alone, even after the passages are clear. Warm boric lotion is used to syringe the sac. Two or three syringefuls are slowly and gently injected, the patient being told to swallow if he feels the fluid in his throat.

At first the fluid mostly regurgitates through the upper punctum, bringing with it flakes of muco-pus. The syringing should be done once a day and the patient instructed to empty the sac by pressure on it four or five times a day, so that it is kept collapsed. At the same time a mild astringent and antiseptic lotion, such as one containing zinc sulphate gr. i. ad ℥i. in a saturated solution of boric acid, should be prescribed for use night and morning. Under this treatment it will often be found that fluid passes into the nose at the fourth or fifth syringing, in which case the syringing is continued at longer and longer intervals until there is no regurgitation on pressure over the sac. In obstinate cases it is a good plan to inject argyrol 10 per cent. gently into the sac and leave it there, but if this is done one must be certain that there is no abrasion of the lining of the passages, since permanent staining of the tissues has been known to result.

If syringing does not bring about a cure the effect of probing the nasal duct may be tried before operation is advised. The passage of the probe does not require an anæsthetic if a solution of 2 per cent. novocaine is injected into the sac beforehand. Cocainising the conjunctiva is not sufficient. The probe is passed along the canaliculus until the inner wall of the sac is felt and the point is then turned downwards so as to engage in the upper end of the nasal duct, when it is pushed steadily downwards. Each probe is left in position a few minutes, then withdrawn and a larger size passed. Only the smaller sizes can be passed without slitting the canaliculus, as the punctum is the least distensible portion of the tract. Care must be taken not to probe if the sac and duct are very inflamed as there is risk that the damage done may only convert a stricture due to swelling of the mucous membrane into a fibrous cicatricial stricture, which will be much more difficult to dilate. Formerly, when syringing and probing had failed, recourse was had to the passage of lead or silver styles which distended the nasal duct and were worn for weeks or even months at a time. This form of treatment is seldom used now, as results attained with it were no better than with other methods, and the style, acting as an irritant foreign body, helped to keep up the discharge and in time led to still more fibrosis around the duct.

If after a fair trial of syringing and probing there is no improvement one must consider the question of operation. The operation, which will certainly remove at once the unpleasant purulent regurgitation and the grave risk of an infection of the cornea, is excision of the lacrymal sac. This is a simple operation and can be performed under a local anæsthetic (novocaine and adrenalin); indeed, it is better so performed as the bleeding can be much more efficiently controlled. If the sac is completely removed healing is by first intention, and the little scar, which follows the direction of the skin folds, is hardly noticeable. The operation has the one disadvantage, however, that it abolishes drainage into the nose and therefore the epiphora is still likely to be trying in windy weather, though it becomes very much less owing to the removal of the infected and irritating discharge. It was this anatomical imperfection of the operation which led surgeons, such as Toti and later West, to devise a means of establishing permanent drainage by chiselling away the bone of the inner wall of the lacrymal sac and establishing a direct communication with the nose here. There are now various operations planned with this end in view. In West's operation the removal of bone is done via the nose and there is no external scar at all, the new passage being kept patent by means of a silver wire passed from the slit canaliculus through to the nose and out at the nostril. This is worn till healing is complete, usually ten days. In the earlier operations the bone was approached through an external incision. In successful cases the results of these operations are very good, a perfect functional return to normal being attained, but they all have the disadvantages that they require a general anæsthetic, the patient is incapacitated from work for a longer period, and in a certain percentage of cases the new passage becomes occluded by fibrous tissue and prolonged dilatation or further operation is necessary.

In some cases, as when acute glaucoma arises in an eye already the subject of chronic dacryocystitis, the closing of the sac becomes an operation of urgency. In these cases the quickest procedure is ligature or cauterisation of the canaliculi, the next best excision of the sac. On no account must any intra-ocular operation be performed in the presence of regurgitation from the lacrymal sac, as there is a grave risk of panophthalmitis and loss of the eye. In a certain number of cases of lacrymal obstruction an acute dacryocystitis arises, for which the patient seeks relief. In the early stages, before the abscess is actually pointing through the skin, every effort should be made to secure resolution with discharge of the pus through the canaliculi. The punctum should be dilated, gentle pressure applied over the sac, and hot fomentations and hot bathings persevered with. In many cases incision or spontaneous discharge of the abscess through the skin may be avoided.

If the abscess is pointing it should be opened at the most fluctuant part, the pus evacuated, and the cavity packed with gauze so as to promote healing from the bottom. In most cases the severity of the inflammation has destroyed the lining membrane of the sac so that the cure is permanent by its obliteration. If some mucous membrane remains a permanent fistula results; it is then best to split up the little sinus and thoroughly curette the cavity, or, if large, dissect out its walls.

Infants with Congenital Obstruction.

In the second group of cases, those occurring in infants, the complaint may be of watering and discharge from the eye or of an acute dacryocystitis coming on soon after birth. One should first try the effect of teaching the mother to empty the sac by pressure and instructing her to do this very frequently so that there is never any large collection distending the sac, at the same time keeping the conjunctiva clean with irrigations of boric lotion. If there is no improvement in the condition after three weeks a general anæsthetic should be given and a probe passed once *without slitting the canaliculus*. This in most cases will remove the epithelial débris blocking the duct and re-establish the natural channel. The operation can be repeated if necessary after three weeks' further treatment.

If an acute dacryocystitis has supervened an attempt should be made to dilate the punctum and express the pus. Otherwise the abscess must be opened and dealt with as described above in adults. If rubber tissue is used for drainage the piece must be large, as small pieces have been known to slip into the cavity and remain undetected for weeks, preventing healing. Ribbon gauze is better for the purpose, but it must be thoroughly wetted with lotion or the dressing will be painful. In some cases a fistula remains and on probing this bare bone can be felt. This always arouses a suspicion of syphilitic or tuberculous disease of the nose and calls for careful investigation and appropriate treatment.

Blockage Proximal to the Sac.

In the rare cases where the blockage is proximal to the sac treatment varies with the condition.

(*a*) If the punctum is apparently absent careful search should be made with a good light and a corneal loupe when a small depression can nearly always be found. This can then be dilated, using a needle at first if necessary. In most cases with care a passage can be found into the canaliculus.

(*b*) Sometimes the punctum opens on to the outer surface of the lid margin and so does not lie in apposition to the globe. This may be remedied by slitting the first part of the canaliculus, taking care to turn the blade of the Weber's knife directly backwards so as to cut the posterior wall, not the roof of the little passage.

(*c*) In senile ectropion a small V-shaped piece of tissue should be removed (either with knife or cautery) from the conjunctival aspect of the lid below the punctum so that the resulting cicatricial contraction will pull this up into position.

(*d*) In cases where the puncta have been obliterated by a burn or other injury, treatment is difficult, as it is almost impossible to reconstruct the anatomy of the part. The epiphora is not likely to be so trying in cases in this group, since the element of infection and consequent irritation is usually absent. If, however, there is great discomfort the removal of whole or part of the lacrymal gland will afford relief. There is no danger of producing excessive dryness of the eye by this procedure, as Krause's glands and the mucous glands of the conjunctiva produce quite sufficient moisture. Usually the palpebral portion only is removed, since this involves so much interference with the ducts from the orbital portion that this latter subsequently atrophies.

(*e*) If a concretion or foreign body (usually an eyelash) is blocking the punctum, this can be removed by syringing or picked out with fine forceps after incising the canaliculus.

A DEATH-RATE FOR MERCHANT SEAMEN.

BY W. E. HOME, M.D., B.SC., D.P.H., M.R.C.P. EDIN.,
FLEET-SURGEON, R.N. (RETIRED).

THE deaths of merchant seamen in 1922 are stated in the Board of Trade's "Return of Shipping Casualties to and Deaths on Vessels Registered in the United Kingdom"[1] for that year. The returns for past years have been sharply criticised, yet there is little change in this now before us. The deaths are grouped according as they occurred among British, foreign, or lascar seamen, but there is no indication of the number of men in any of these groups, while the aggregate stated for the total employed is not claimed in the return to do more than "furnish an approximate basis for estimating the variation in the risks" from year to year. Further, in this return, as in its predecessors, tubercle and cancer are classed as Constitutional Diseases, and beri-beri as a Specific Fever. Why the Registrar-General's classification of 1922 was not adopted, grouping tuberculosis with the "Epidemic, Endemic, and Infectious Diseases," and beri-beri with the other general diseases, like cancer and scurvy, does not appear. The numbers of British, foreign and lascar seamen, making up the total of the "first crews" of ships, were kindly provided by the Board of Trade, but it remains a mystery why these figures should not be printed in the return and approximate death-rates added for "estimating the variation" in health occurring from year to year. If the Board of Trade pays any attention at all to these figures of deaths, it must have some sort of death-rates prepared for office use. The separated figures for 1922 were: British, 169,943; foreign, 11,563; lascars, 55,266; total, 236,772. Having these, it is possible to give an estimate of the death-rates for each class of seamen. Another curious feature in the return for 1922 is the alteration of the totals given in the last return for "first crews" in 1920 and 1921, from 278,593 and 274,216 to 245,168 and 242,440, without comment; possibly the men in fishing vessels are now omitted; but surely if this change has been made, it should have been so stated. The classified totals of deaths, with death-rates as estimated, are here given (see Table).

That there are two statements of death-rates will be noted with surprise. The first is calculated by the help of the "first crew" figures, with far too many men, 236,772, shown. This death-rate is consequently too low. The second has been based on the census of seamen in British ships on June 19th, 1921, and

---

[1] H.M. Stationery Office. 1924. 3s.

has been worked out since the leading article in THE LANCET of March 14th last drew attention to that report. It shows a total of 151,911, and the death-rates worked out thereon are much higher. The "first crew" figures show the first crews of all ships that went to sea in that year, but gives no indication of the period during which they were in service; if one ship is withdrawn and replaced by another, with the old crew simply transferred, these men are counted twice, and so on. The census figure tells how many men, on June 19th, 1921, were employed on British ships all over the world, and obviously should give a better idea of the average number of seamen employed daily throughout the year. Unluckily the census was taken, as the report states, "in a period of acute depression in shipping, accentuated by the coal dispute." So its aggregate is probably too low. Further, it may be urged that its figures do not apply to 1922, when the deaths in the table occurred. That also is true, but "nihil est ab omni parte beatum," and no better method seems available for estimating the death-rate of merchant seamen. Possibly the true rate is a mean.

There were in 1922 some 100,000 British seamen. Of these, 5 were murdered, 30 committed suicide, 37 were lost through drink, 224 by casualties to their ships (founderings, collisions, missing, &c.), 266 by accidents aboard or on shore, and 374 by diseases, of which the most important were tubercle 46, pneumonia 41, and enteric 19. Of the next most numerous group, lascars, there were some 50,000. Of these, 2 were murdered, 20 committed suicide, none died through drink, 127 were lost by casualties to their ships, 60 were killed by accidents, nearly all on board their ships, and 219 by diseases, with tubercle 44 and pneumonia 42, as the most notable. Foreign seamen, about 12,000, had the highest death-rates from alcohol, from digestive and from circulatory diseases. Lascars had the heaviest rate for suicide, and an enormous excess (double) over British seamen from tubercle and pneumonia, which would appear connected with the lesser statutory cubic space, 72 cubic feet, prescribed for them in ships, as compared with the 120 cubic feet the British or foreign seaman must have. In sailing ships in 1922 there were no deaths from disease, but the fatal accidents were three times as many as in steam, and the total deaths 50 per cent. higher.

The Health Return of the Navy for 1922 is not yet available, but if the death-rates of 1921 may be taken as a guide, the British seamen of the merchant service appear to have a mortality over 50 per cent. higher from disease, and three or four times higher from accidents than are those of their seafaring brethren of the Royal Navy; but we do not know how far the ages of the men in both services are similar, so these figures are not strictly comparable.

As it is obvious that the death-rates of the Mercantile Marine are not exactly known, but are probably very high, I hope it will appear to everyone that it is time some thorough official study of the deaths of seamen should be undertaken, that accurate and informing statistics should be prepared by a Government department to show what the death-rates from diseases and accidents are, and that some planned endeavour to reduce the present excessive rates should be initiated. Of this there is hope, for the Prime Minister has stated that the Mercantile Marine Branch of the Board of Trade is in this matter in close touch with the Ministry of Health. There is in the return before us no evidence of such close touch (it was issued in 1924), so for what may come out of this coöperation we may perhaps do well to thank Mr. B. Smith, M.P. for Bermondsey (Rotherhithe), whose question produced that hopeful answer in the House. It will probably be expedient for the National Union of Sailors and Firemen to watch carefully the outcome, for there is no other body whose members are so vitally interested.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

(Continued from p. 773.)

EVIDENCE OF THE INDEPENDENT ORDER OF RECHABITES.

(App. VIII.) The Independent Order of Rechabites is a Registered Friendly Society established in 1835. Membership of the Society is open to both sexes subject to the condition that all members must be abstainers from intoxicants. Evidence was given by Mr. Joseph Cave, the High Chief Ruler, and Mr. J. P. Illingworth, a Director of the Order. These witnesses gave evidence similar to that of previous witnesses (Manchester Unity and Foresters) on the following points:—

(1) That administration through branches (in this Order called Tents) was the most satisfactory and most democratic method.

(2) That sickness and disablement benefits should not be increased, it being desirable that all extra provision (Q. 6107) should be made through voluntary agencies.

(3) That women on marriage should be given the ordinary free year of insurance.

(4) That deposit contributors should be distributed amongst Approved Societies. (They stipulated, however, that members allocated to their society should comply with their conditions of membership.)

(5) That pooling of surpluses in general was undesirable except possibly amongst branches of the same society.

Dental and Convalescent Treatment.

(App. VIII., 33.) Dental treatment was urged as desirable, but the witnesses hesitated with the present rate of contribution to suggest that it should be made a normal benefit under the Act. With dental treatment they coupled convalescent treatment and also optical treatment as "additional benefits" which should be administered as such by Approved Societies until some comprehensive scheme of National Medical Service is practicable.

Consultant and Specialist Services.

(Q. 6362.) First in order of precedence for new services this society place consultant and specialist services, and not dental treatment as previous witnesses had done. It was proposed that some portion of the contribution should be set aside for these additional services, which they considered that all insured persons entitled to the ordinary medical service should enjoy.

The Panel Service.

As to this, this society's evidence was:—

> (App. VIII., 25.) It can almost unreservedly be said that our relations with the medical profession have been most cordial, and recorded cases of complaint have been very few indeed. Occasional cases of difference have been found to be due to misunderstanding either by the member or the doctor, and have been generally satisfactorily settled.

The witnesses made reservations with regard to medical certification, stating that difficulty was experienced in getting certificates in cases where a doctor's recommendation—e.g., for dental benefit—was desired. The witnesses appeared (Q. 6390–7) to suggest that a doctor was under an obligation to give a written recommendation for dental or other extra treatment, even though the insured person was not incapacitated. It was pointed out to the witness in a series of questions that the doctor's obligation† was merely to add a recommendation to a certificate of incapacity.

---

* In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247–8); The Provision of Medical Benefit (Feb. 7th, pp. 301–3; Feb. 14th, pp. 355–6; Feb. 21st, pp. 403–5); Financial Provisions of the Act (Feb. 28th, pp. 454–7); Medical Certification and the Regional Medical Staff (March 7th, pp. 508–9); The Approved Societies and the Money Benefits (March 14th, pp. 564–5; March 21st, pp. 623–4); Evidence of the Hearts of Oak Society (March 28th, pp. 677–9); Evidence of the National Conference of Industrial Assurance Approved Societies and of the Manchester Unity Approved Society (April 4th, pp. 731–3).

References to the official statement which has been issued as an appendix in four sections are given thus; Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

Why the Contributions for Women are Less.

With regard to the recommendation (App. VIII., 2) that the women should pay the same weekly contribution as men, Sir Alfred Watson pointed out, in the form of a question, that :—

> (Q. 6126.) In the case of men the contract is practically one for the whole of life up to the age of 70, with heavy claims after 60, while in the case of women the contract terminates in the vast majority of cases at or a short time after marriage, with no old age liability.

Medical Institutes.

The society proposed that medical benefit should be given by medical institutes on the same terms and conditions as by panel doctors, and that the present embargo should be removed to permit the setting up of new medical institutes where such are desired and where circumstances appear to warrant such action.

With regard to this recommendation Sir John Anderson sought by a series of searching questions to discover what advantage would accrue to insured persons if this recommendation was accepted. He elicited from the witnesses that the medical institute was a system devised by friendly societies before there was any general medical service for insured persons, and that the doctors in many cases were salaried officials and he suggested that the insured person would, in effect, be deprived of free choice of doctor.

> (Q. 6338.) There is a normal system which is treatment through what is called panel doctors. If you want to provide something different, some exception from the normal system that exception surely must be justified on its merits . . . I want to see some advantage from the point of view of the insured person. It is obvious, is it not, that when the National Insurance Act was passed the provision which it contained with regard to existing institutes was inserted to prevent injury to institutions already in existence ; but there was a very clear indication that no more of these institutes were to be recognised for the purpose of providing benefit under the Act. Now you suggest that barrier should be removed. I want to know what are the grounds from the point of view of the insured person for advocating that course. Are there any ?—The only grounds are that it was a system recognised at the inception of the Act, and if it was good enough to be recognised then it is good enough to be continued. (Q. 6345–6.) Does not the existence of an institute of the kind you are referring to imply some kind of lay control over the work of the doctor ?—I do not think so, in the institutes that are in existence at the present time.
>
> Q. There is nothing whatever to prevent the doctors from coming together in partnerships or in clinics or in any sort of way they like for the purpose of securing professional coöperation in carrying out their work. The essence of an institute is that there is lay control . . . Is that not so ?—It may be in certain cases, but that does not apply to all medical institutes.

It appeared from later answers that the recommendation was largely due to the unique system at Leicester, where members of an institute can go to any doctor on the panel and free choice of doctor is thus secured. It was also (Q. 6371) suggested that the accommodation at the institutes in Leicester was superior to the average run of general practitioners' consulting rooms, and that the institutes lent themselves to organisation amongst the doctors and to the obtaining of second opinions. The witnesses explained (Q. 6371) that they had no particular connexion with institutes, and said that (Q. 6342) on the whole it was not a matter that they greatly desired to press.

Medical Service for Dependants.

(App. VIII., 30.) The Rechabites consider this to be in the interests of public health, but—

> In view of the many difficulties which immediately present themselves when this question is considered, we make no further comments beyond expressing a general approval of the scheme prepared by the National Conference of Friendly Societies.

EVIDENCE OF THE RATIONAL ASSOCIATION FRIENDLY SOCIETY.

The witnesses in this case were Mr. Jonathan Duncan, the Secretary, and Mr. Bailey, Assistant Secretary. The Rational Association Friendly Society was established in 1837. It had a scheme of medical benefit prior to the National Health Insurance Act. It is a centralised society with branches. The branch secretaries are subject to the control of the central office, but have a considerable discretion allowed to them. The society is valued as a whole, each member being entitled to share equally in any surplus, but the men and women members are dealt with in separate compartments, with the result (Q. 6413) that the women get much less of the surplus than the men.

The evidence embraces recommendations similar to those made by other societies as to the limitation of cash benefits, and the free year's insurance to women on marriage, and emphasises the objection to pooling surpluses. The importance of providing dental treatment as a uniform statutory benefit is urged (with the suggestion that it should be 50 per cent. of the cost up to a maximum of £3 10*s*. in any one case), and it is recommended that Insurance Committees should continue their present work and (Q. 6617) should administer dental benefit.

Doctors as the Spending Department.

(App. IX., 35.) In regard to medical certification the experience of this society is that :

> A large number of medical men are either deceived by the detailed symptoms of the insured person or they do not diagnose cases correctly, and hence a number of persons are treated and take drugs for diseases from which they do not suffer.

As doctors are the " great spending department " errors on their part are costly and greater care in certification is urged.

> (Q. 6517.) Would you say that if National Health Insurance was pooled and administered with a common fund there would be any probability that the claims would be higher than they are at the present time ?—I could not say whether there would be any probability of that. It would depend on how it was administered and on the doctors. We are always in the hands of the doctors . . . They are the great spending power.

With regard to the rather general criticisms in the evidence of this society on the medical profession Sir Humphry Rolleston elicited that these were based on the published reports of the Ministry rather than on the society's own experience.

> (Q. 6620–5.) It must be obvious to you that at the commencement of a disease it is common to the whole medical profession not to be able to say in many cases what is going to be the result. It strikes me that perhaps the wording of this is not intended to express the reflection which might be read into it ?—All we can say is that in these cases people are certified as being incapable of work and as suffering from certain diseases. We also assume that they are taking drugs for those diseases, but they are certified as capable of work by the regional medical officer. They were not suffering from those diseases, so that it logically follows they have been taking drugs for diseases from which they did not suffer. Was there any possibility that they might have been cured of those diseases ?—There may have been. You do not introduce that alternative ?—No ; but sometimes we get a first diagnosis and then we get a different one later, which shows, of course, that the first diagnosis is not always correct.

The last answer prompted Sir Humphry Rolleston to remind the witness that it is a very common thing for a disease to change and for complications to occur.

---

† The Regulation provides as follows : " (Rule 16 of the Medical Certification Rules : The practitioner shall, if so requested by the patient, include in the next medical certificate issued by him under these Rules a statement of any form of special medical or other treatment which he has advised the patient to obtain in any case in which he has been informed by the Approved Society of which the patient is a member that it is enabled under its scheme of additional benefits to defray the whole or a part of the cost of that treatment.) "

Free Choice of Doctor.

(App. IX., 34.) After reciting that this society is entirely opposed to any curtailment of the right of insured persons to a free choice of doctor or of facilities to lodge complaints, this evidence contains the curious statement that the society

> is opposed to any demarcation of streets into areas in any large centre for the purposes of medical benefit, as such an idea savours of pauperism.

(Q. 6677–80.) The witnesses had heard that "something like this was contemplated," which led Sir Alfred Watson to remark that dissent was being expressed from a proposition of the existence of which the Commission was unaware.

Medical Benefit in Old Age.

(App. IX., 26.) This society's evidence contains a recommendation, already made by other societies (but not hitherto included in our extracts), that:

> As many persons are discharged from employment at age 60 or 65 (thus losing their right to medical benefit after their free term has expired), who would otherwise have been entitled to medical benefit throughout life had they continued employment until 70 years of age, it is considered that such persons suffer hardship. It is, therefore, recommended that legislation should be promoted to enable such persons to pay up to the age of 70 an equivalent sum (to include cost of administration) to that paid by insured persons, and after age 70 to be entitled to free medical treatment.

EVIDENCE OF MINERS' SOCIETIES.

Scottish Miners' Federation Approved Society.

(App. X.) The principal evidence of this society was on the subject of the hazardous nature of the miners' calling, the heavy incidence of sickness, and the physical deterioration which causes heavy claims for prolonged disablement benefit.

After-effects of Accidents.

(App. X., 7.) With regard to accidents, claims arise under the National Health Insurance Acts in respect of subsequently recurring periods of disability. The burden of medical evidence points to the fact that the primary cause of these recurring periods of incapacity is either closely allied to the seat of injury or directly attributable to the original accident.

(App. X., 9.) On this question the following was quoted from lectures delivered by Mr. (now Sir) Alfred Watson in 1911–12:—

> The average weeks of sick pay of colliers were 1·62 per member per annum taking all ages, while the average weeks of sick pay of all other classes were 1·20. . . . The colliers had a great amount of sickness liability due to compensated accident cases . . . The purely sickness experience showed an excess in the case of the miner of about 35 per cent. whilst his industrial accident liability was about six times the average of the other classes. . . . There is more sickness proper among the heavier risk occupations than among the normal grades, and this illustrates the fallacy [of the statement] . . . that if the industrial accident liability is eliminated everybody is brought to the normal condition, justifying equality of financial treatment.

Prolonged Absences.

(App. X., 5.) One suggested cause of heavier sickness claims was that—

> the miner, owing to the strenuous nature of his life, is inevitably compelled to relinquish his work at the onset of the disease and does not resume until he feels thoroughly well equipped to undertake the arduous task of coal-getting,

whereas persons in less exacting occupations can resume work at a stage of recovery which may not represent normal fitness.

Derelicts.

(App. X., 6.) The industry is productive of a considerable number of derelicts; when physical deterioration has set in they rapidly become a permanent charge on the funds of the society.

Objection to Segregation.

(App. X., 11.) The witnesses objected to the present system of segregation of societies, each separately valued, some enjoying their own surpluses while others—e.g., purely miners' societies—had none. A flat rate of contribution should, they considered, produce a universally flat rate of benefit. (16.) The most effective arrangement would be to reorganise the scheme on a territorial basis.

Miners who Join other Societies.

(Q. 6837–40.) The witness represented the only miners' society in Scotland. There are 46,000 miners in the society and a larger number than that spread over other societies in Scotland. It results that some miners are working side by side with others who, when sick, receive more favourable sickness payment.

> Q. That is all because the other societies have chosen to admit the miner, is it not?—Yes.—Q. They are not bound to take him, nor were the 46,000 in your society compelled to go to you. They could have gone to these other societies if they had chosen?—Yes.

This led a member of the Commission to suggest that there did not seem to be any grounds for a grievance.

(Q. 6944.) It appeared from later questions that what was objected to was the existence of two types of society and that the witness could not object to a system in which each society represented a fair sample of the population.

Pithead Baths.

(Q. 6756–7.) The witness agreed that pithead baths would be a great advantage, but said frankly that the difficulty was to get the men to take the same point of view. Opposition had been offered both by the employers and the men. It was clear that the severe changes of atmosphere, the heat below ground, and the walk home, often in damp clothes, were potent causes of sickness. The pithead bath-houses, to be effective, should contain drying stores for changes of clothes for men coming on or leaving off work.

Double Refereeing.

(Q. 6690–1, 6707.) The society have their own referees and are not prepared to abandon these arrangements. Some of their members appeal against the regional medical officer's decisions and the society allow this. The suggestion which had been made that in the event of a dispute the regional medical officer's opinion should be final was one which they were not prepared to accept.

(Q. 6692.) As to certification generally, the witness did not wish to make sweeping charges, but felt confident that there was a proportion of careless doctors.

> I expect that that proportion will continue for all time. Doctors seem to me to be just like ordinary humanity. Some are only professionally intelligent, and are hopeless in other respects. That is our experience, but it applies only to a very limited number.

SCOTLAND.

(FROM OUR OWN CORRESPONDENTS.)

The Eighty-Fourth Session of the Edinburgh Obstetrical Society.

THE winter meetings of the society for 1924-25 evoked a number of instructive and scientific papers. The session was opened by the President, Prof. B. P. Watson, who delivered an illuminating presidential address on the teaching of obstetrics, in which the method of instruction in Edinburgh was stated, and various points taken to show how that instruction might be improved with accruing benefit to both patient and student. The ideal method of training would be hard to attain, but should always be kept in mind as the acme to be reached. In January Prof. Louise McIlroy (London), Prof. R. G. McKerron (Aberdeen), and Prof. Munro Kerr (Glasgow), as guests of the society, took part in a discussion on the treatment of placenta prævia, the subject being introduced by an analysis of the treatment of 254 cases at the Royal Maternity Hospital, Edinburgh, the cases having been collected by the President and Dr. Douglas Miller. The other papers read during the session included both obstetrical and gynæcological subjects, and were both practical and scientific in character. Prof. Ranken Lyle (Newcastle) read a very interesting paper on neurasthenia in relation to chronic pelvic pain, which provoked much discussion. Mr. D. M. Grey gave a communication, abundantly illustrated by numerous lantern slides, casts, and skulls, on plagiocephaly, and asked if it might ever be a birth deformity. No satisfactory answer to the question was elicited either in the affirmative or negative. At one meeting two papers were read on puerperal sepsis, Miss Jessie Eeles treating the subject from the scientific aspect and discussing the pathology of the disease in full; Dr. W. A. Dafoe gave an account of an epidemic of puerperal sepsis due to the *Streptococcus hæmolyticus* in Toronto, and the means taken to prevent further infection. Dr. Douglas Miller described in full, with lantern illustrations, two cases of Krukenburg tumour of the ovary, which had come under his notice, and Dr. Chassar Moir gave an account of investigations pursued by him on the question of the clinical activity of dextro- and lævo-rotatory hyoscine in twilight sleep.

Proposed Memorial to the late Dr. C. B. Ker.

A subscription list has been opened to provide a memorial to the late Dr. C. B. Ker, of the City Hospital, Edinburgh, and as far as possible all past and present members of the medical and nursing staff of the hospital have been circularised and invited to contribute. The appeal is being issued in the names of Dr. Alexander James, the consulting physician to the hospital, Dr. W. Robertson, the medical officer of health of the city, Miss Thomas, the matron of the hospital, and Dr. A. Joe, the senior assistant. It is proposed that the memorial should take the shape of a monument at Dr. Ker's grave at Morningside Cemetery and, if funds permit, the erection of a plaque in the hospital. There are doubtless many old City Hospital residents, both in this country and abroad, desirous of contributing whose addresses are not known, and all such are invited to send donations to Mr. Macdonald, Steward, City Hospital, Edinburgh.

Royal Aberdeen Hospital for Sick Children.

The directors of this hospital have decided to proceed at an early date with the erection of a new hospital. An excellent site has been obtained at Forresterhill, forming part of the ground on which it is hoped to concentrate the hospitals of the city according to the "joint hospital scheme" at present under consideration. Plans have been finally approved for a new children's hospital of 132 beds, with out-patient and other special departments. While every consideration has been given to economy, it has been found that in order to get a really good and well-equipped hospital in which the treatment of the diseases of children can be carried out according to modern standards of efficiency, it will be necessary, at the present high cost of building, to face an expenditure of not less than £110,000. Funds already collected and promised amount approximately to £65,000, and the directors are now issuing an appeal for the remaining £45,000. At a meeting of the honorary staff of the hospital it was resolved that a special appeal be made to all members of the staff, to old residents, and to any graduates of the University of Aberdeen who may care to contribute. It is confidently hoped that a sum sufficient for the construction or for the equipment of some special part of the hospital may be collected. The deplorable condition of the present hospital is so well known to graduates, and particularly to old residents, that it is not necessary to enlarge on it here, but it may be emphasised that the age and general unsuitability of the present building hamper not only the efficient treatment of patients, but the adequate instruction of medical students and nurses. The provision of a new hospital will, therefore, benefit not only the community, but also the Medical School in Aberdeen. Contributions marked "Staff Fund" may be sent to Miss Hill, lady superintendent of the hospital, who has kindly promised to acknowledge their receipt.

MEDICINE AND THE LAW.

MEDICAL MEN AS CORONERS.

It appears that in some districts there is a tendency to return to the practice, at one time universal, of appointing barristers or solicitors as coroners instead of the medical men who more recently and more wisely have been selected. Indeed, The Lancet is informed that at least one local association of lawyers has approached the electing body of its district with a view to furthering that end. Most of such disinterested persons as hold the view that a lawyer ought to make a better coroner than a doctor are more familiar with the reports of inquests in the newspapers, the majority of which relate to sensational cases of homicide or suicide, than they are with the more everyday duties of a coroner's life, with the inquests where there may be little to report, but where it is important to determine the precise cause of a death, and with the circumstances in which the coroner has to decide in a case where no medical man has recently attended the deceased, whether there has been a death which ought to be explained by evidence in open court. To advocate the desirability in the public interest of appointing as coroners medical men of experience has been the policy of The Lancet ever since its foundation, always with the admission that a double training in medicine and in law may render a coroner more efficient than one who has been trained in medicine alone. If, however, we repeat some of the arguments in favour of medical coroners, we shall do so most forcibly by asserting, and by challenging contradiction in doing so, that to fit a man for the performance of a coroner's duties no portion, or scarcely any, of his training to be a general practitioner will have been irrelevant, or will fail to assist him at one time or another, whereas the amount of legal training that he needs is very small. He would profit, no doubt, by having acquired by practice some skill in examining witnesses in court, and in detecting their weaknesses or tendency to deceive the court. This would help him at a few inquests at first, but he would soon acquire it with practice. As a rule, however, a coroner deals with very simple witnesses who have no desire to deceive him. Where they give evidence as to the manner in which a death has taken place, his appreciation of their statements as a medical man familiar with death and its causes will be invaluable and indeed indispensable. It must be remembered that he has to deal with other witnesses as well as with medical men in tracing the cause of death. As to knowledge of law, the training an intending coroner would undergo as a student seeking a call to the Bar would include the study of Roman Law, equity and conveyancing, the law of torts and of contracts, criminal law, and the law of evidence. None of the first named could in any way, except perhaps as mental training, be of use to him as a coroner. With the criminal law he has no need to be familiar except with that limited portion of it that relates to murder and manslaughter, and in any case of alleged murder or manslaughter the strict application and enforcement of the law is ultimately the function of magistrates and judges, not of the coroner. A general knowledge of the law of evidence in criminal cases should, of course, be possessed by every coroner, but it must be realised that he is not bound to apply it strictly. He conducts an inquiry, not the trial of a prisoner, even though a person may have been arrested in connexion with the death which is the subject of the inquest that he is holding. He does not have to apply the rules of evidence as they would affect such a person if he were before magistrates or a court of assize. Reference has been made to a coroner's duties with regard to lay witnesses, but his most important guide in all cases will be the testimony of medical men, and he may have to discriminate between conflicting medical witnesses. It may, in short, be said that nothing or little that he will have learnt as a doctor will have been superfluous, and that the knowledge of the law that he will find necessary can be acquired by him with a little application, and by using his trained intelligence with a few months' or even with a few weeks' study. The importance of medical training for a coroner, who has to decide whether an inquest is necessary, and who, until he has so decided cannot order a post-mortem examination to be held, has been referred to above and cannot be stressed too strongly. In deciding to hold an inquest he has often to meet the opposition of relatives and of others who, for various, but not necessarily guilty, motives, will desire that no public inquiry should be held, and he has to avoid two opposite and distinct errors, that of holding an inquest unnecessarily, and, on the other hand, that of not holding one, which in the public interest, and perhaps in the interests of law and justice, ought to take place without delay.

EXPERIMENTAL RICKETS.

CEREALS have long formed the major part of the diet of man. From a physiological standpoint they have been considered almost entirely as a source of energy, of carbohydrate, and of protein, and it is on this basis that their dietetic value has been appraised. Apart from differences in vitamin content there has hitherto been no reason to suppose that there are important differences in food value amongst the natural cereals, except such as can be explained in terms of their physiological constitutents.

Prof. Edward Mellanby, in a green book just published under the auspices of the Medical Research Council,[1] describes experimental work which demonstrates that various common cereals have different effects on the growing puppy and that these differences cannot yet be explained on the basis of their known constituents. The report deals with the special subject of the interaction of food factors on the growth and hardening of bone.

The deposition of calcium phosphate in growing bone is not, according to Prof. Mellanby, influenced greatly by the amounts of calcium and phosphorus in the diet, but mainly by the presence in the diet, among other factors, of a calcifying vitamin, the anti-rachitic vitamin. Another important food constituent influencing bone calcification, but in an opposite sense to this vitamin, is found in cereals. When the diet is deficient in anti-rachitic vitamin, increasing the amount of cereal brings about worse-formed bones if other factors of diet and environment remain constant, and qualitative differences among the effects of various cereals have been made out. Oatmeal, which contains more calcium and more phosphorus than the other cereals tested, has yet by far the worst influence on bone formation, and then maize and barley, rice, and wheaten flour in that order. The germ of wheaten flour, when added to the diet in sufficient quantities, also interferes with bone calcification. The detrimental effect of cereals on the formation of bone is antagonised by cod-liver oil, even in small quantities, by whole milk in fairly large quantities; butter is of comparatively small value unless accompanied by a fairly high calcium intake. The exposure of the animal eating the cereal being tested to ultra-violet radiations, or even the exposure of the cereal itself to the same radiations, also antagonises the rickets-producing action.

The methods whereby cereals produce this detrimental effect on bone formation has been studied, though no conclusive results have yet been obtained. In one cereal tested (oatmeal) there has been found a chemical grouping which, after digestion and absorption of the grain, is capable of interfering with bone calcification. This substance is thought to be associated with the fatty acids. It can be obtained by saponification of oatmeal with soda and extracting the acidified mixture with petrol ether.

From the results of these investigations it is deduced that the amount of calcium and phosphorus in food is of but secondary importance in the control of the deposition of these elements in growing bone, although, of course, there must be a sufficiency of the salts for the formation of perfect bones. In view of the evidence of interaction and balance among food constituents provided, it is held that the value of the expression "optimum calcium content of a diet," commonly used in dietetic discussions, must be doubted, since the optimum varies every time the other elements of the diet are changed.

Practical Points.

One or two practical points arising out of the experimental results are discussed, assuming that these results may be applied to man. For example, the challenge that fine races of men have been reared on diets of which oatmeal forms a large part has to be met. Prof. Mellanby suggests that probably the diet of such races also included much food rich in anti-rachitic vitamin, such as milk, eggs, and fish of the fatty variety, including herring, salmon, mackerel, &c. In tropical countries, where cereals such as rice, maize, millet form a large part of the diet, the sunlight may be an important factor in antagonising their detrimental influence. Experimentally, perfect bone formation can be obtained in puppies, even when large quantities of oatmeal are eaten, if the rest of the diet be adequate. In this country, where the average diet is either deficient in or contains a border-line quantity of anti-rachitic vitamin and calcium, and where sunshine is negligible, the ingestion of oatmeal during pregnancy and lactation of women and in growing children is considered by Prof. Mellanby as probably harmful.

Another point of practical dietetics centres round the controversy of wholemeal bread. Prof. Mellanby holds that from the point of view of rickets and its allied problems the question of whole-meal versus white bread is probably of little practical importance.

MENTAL HOSPITAL REPORTS.

IN recent years much has been done by those who have charge of mental patients to ameliorate the conditions under which they are obliged to live, and a survey of mental hospital reports reveals the tendency of public authorities, in all parts of the world, to adapt circumstances in accord with the modern attitude. It is gratifying to see how much attention is being devoted to the extension of the possibility of voluntary treatment, as it is by progress along this line that the old fears and misgivings of the public will best be removed.

Vol. II. of the annual report of the London County Council on *Mental Hospitals and Mental Deficiency* reveals the fact that there are more than 18,000 persons under the care of the L.C.C. in mental institutions. This is a slight increase on the previous year, mainly due to parish patients. The average of admissions and of discharges as "recovered" remains fairly constant, 881 cases having been so discharged in the year under review. Attempts have been made to improve the footgear, clothing, and laundry of patients in these institutions, and to allow for individual variations in the trimming of frocks. Arrangements have been made for a greater variation in the dietary, with due attention to the caloric value of the food provided. The alterations in the laundry have cost £5000. Several interesting experiments have been initiated; at Claybury a trained masseuse has been appointed to see if the provision of regular massage is of advantage to the patients. The experimental appointment of an honorary lady visitor at Horton, to act as a liaison between inmates and the outside world and as a friend to friendless patients, has been so successful that similar appointments are being made at the other

Experimental Rickets: The Effect of Cereals and Their Interaction with Other Factors of Diet and Environment in Producing Rickets. Special Report Series No. 93. H.M. Stationery Office. Pp. 66. 3s. 6*d*.

hospitals. For the mental defectives the occupation centres provided by voluntary bodies have been found helpful and the scouts and guides movement has proved a valuable aid to moral tone.

In *New South Wales* some (8000) insane persons were under official cognisance at the end of June, 1924. The institutions available appear to be overcrowded, particularly in the female and the criminal departments, with the regrettable result that certifiable cases have in some instances to remain in gaol. There is also insufficient accommodation for inebriates. A curious omission in the legislation dealing with this department of public health is the absence of any provision for dealing with mental defectives. The Lunacy Act, passed in 1898, has not yet been amended, although continuous representations have been made on the subject. New South Wales is concerned with the same problem as that which is exercising all legislatures since the modern developments of psychology have drawn attention to the need for competent treatment of mild and incipient cases. The proposed amendments provide for the early cases at general hospitals and for an intermediate class of patient to be admitted to a mental institution at his own request, to be detained there if it subsequently appears necessary in his own interest. Although voluntary boarders are found in all the mental hospitals, their position is not legalised. Some provision is made for the "borderline" case by two reception houses for slight and transient mental disturbances and for alcoholic cases, and by the psychiatric clinic at Broughton Hall. The former saved some 600 persons from the necessity of certification during the year. At the latter 132 uncertified patients can be accommodated, and the clinic works in harmony with the out-patient department of a hospital. The accommodation provided by these institutions is, however, quite inadequate for the needs of the community, and it is to be hoped that our brethren in New South Wales will be able to put through the proposed improvements in the law without further delay.

In his annual report for the year 1924, the physician-superintendent of the *Aberdeen Royal Asylum* draws attention to the need for making the voluntary boarder system more widely known among the public, as many cases of certification could thereby be avoided. There is also need for reform in the financial arrangements for rate-aided voluntary boarders; at present the parish councils only receive the lunacy grant if certification has taken place, so that poor persons are not encouraged to seek the early help provided by the voluntary system. One-quarter of the patients admitted during the year were suffering from depressive conditions, while dementia præcox and senile dementia followed next in relative incidence. The number of senile dements has increased very considerably in the last few years and it is difficult to find accommodation for the cases desiring admission. A noteworthy feature of the year's work was the performance of 13 major surgical operations. In the laboratory research on fractional test-meals and on blood-sugar is being conducted.

A similar increase in the number of senile cases is reported from Edinburgh by Prof. G. M. Robertson in the annual report of the *Royal Hospital at Morningside.* The nursing homes, established in connexion with the institution for patients suffering from early and curable forms of mental disorder, are still proving a most successful and necessary department of the work. The patients are received in these houses under the care of their own practitioner but are under the general supervision of the Board of Control; 40 per cent. of the patients entering the mental hospitals of Scotland do so as voluntary boarders and the percentage is steadily increasing. In Edinburgh the difficulty with regard to rate-aided voluntary patients has been met by joint action on the part of the parish council and the managers of the institution. The treatment of general paralysis by malaria is continuing to give satisfactory results; Prof. Robertson suggests that the therapeutic factor may be the rise of temperature and that the fall of 27 per cent. in the deaths from this disease, which began in 1919, might possibly be correlated with the epidemics of influenza with high temperature which occurred in that period. The pathology of pellagra is being investigated in the laboratory.

TUBERCULOSIS SOCIETY.

PROVINCIAL MEETING AT CAMBRIDGE.

A PROVINCIAL meeting of this Society was held at Cambridge from April 2nd to 4th, in the Pathological Lecture Theatre, lent by Prof. H. R. Dean.

On Thursday, the 2nd, Prof. W. E. Dixon gave a lecture on the

Treatment of Disease with Heavy Metals and Bactericidal Agents.

He pointed out that drugs were employed in tuberculosis for one of three purposes: To attack and prevent the growth of the tubercle bacillus or other organisms with which the disease might be associated; to neutralise toxins; or to remove or relieve symptoms. He had confined himself in his paper to a consideration of the first group. The ideal for which they were searching was for an internal antiseptic—i.e., for something which would prevent the growth of the tubercle bacillus without injury to the host. The antiseptic action of most of the ordinary antiseptics, such as phenol and the coal-tar derivatives, was greatly lessened by admixture with serum, and when injected into the animal body they destroyed the tissues before destroying the parasites. Any beneficial effect that coal-tar derivatives might have upon tuberculous patients was therefore not due to their direct influence upon the tubercle bacillus. Essential oils had also formed the basis of many so-called cures, but, like other specifics, they failed in the hands of the sceptical physician. Favourable results had been claimed for calcium therapy, but calcium deficiency was a well-known condition of many diseases, including tuberculosis, and the good results were probably obtained not by influencing the cause of the condition, but by limiting inflammatory exudation. Various compounds of arsenic had been tried with widely divergent opinions as to their value. Careful experiments with some of the more likely organic arsenic derivatives had, however, shown that they had no action on the pathogen city of the tubercle bacilli, and no favourable influence on the disease. True chemo-therapeutic agents, on the other hand, had a specific selective action on certain tissues and bacteria which was probably physical rather than chemical, while their disinfectant action was increased rather than retarded by admixture with serum. Two groups of organic compounds were especially remarkable for their chemo-therapeutic action on bacteria: hydrocupreine, certain derivatives of which had an absolutely specific effect on the pneumococcus and diphtheria bacillus, and acridine, more especially its most recent derivative, rivanol, injections of which had been shown to cure streptococcic infections in mice. Unfortunately, the chemotherapeutical substances which were known to act on bacteria were without value in tuberculosis, the destruction of the tubercle bacillus presenting the double difficulty of the fatty protective envelope surrounding it, and of the small blood-supply to the tuberculous lesion. Of the various metallic compounds for which success had been claimed three were especially noteworthy: cerium salts, copper salts, and gold. The first of these were used in France by a small section of workers, but in the speaker's opinion the evidence as to their value was not convincing. Copper compounds had had a tremendous vogue, but so far they had not proved of much use except in vitro. Egger had shown that the influence of copper upon tuberculous tissue was strictly local and that on account of the increased susceptibility of the vascular nervous system around tuberculous tissue the action of the copper was greater than in normal tissues. The gold compounds which had been used included aurocantan, a cantharadinate of gold which proved to be too toxic for use; krysolgan, a compound introduced by Feldt, the clinical effects of which were both hopeful and inspiring; and sanocrysin, the gold cure recently introduced by Moellgaard. Like its predecessors sanocrysin retarded the growth of tubercle bacilli in glycerinated bouillon in a strength of 1 in 1,000,000, but the speaker had not discovered how the action of this substance was affected by the addition of serum. Sanocrysin was now on its trial; the recorded experiments were suggestive, but certainly not conclusive, and clinical records of treated patients should be kept for years before the true value of a remedy for tuberculosis could be gauged.

At the same session Dr. J. E. A. Lynham, radiologist to Mount Vernon Hospital, read a paper on the

Use of X Rays in the Diagnosis of Pulmonary Tuberculosis.

He mentioned certain conditions as essential for satisfactory screening: the room had to be quite dark; the controls within easy reach; the fluorescent screen must be the best procurable and be protected with thick lead glass; the diaphragm must be rapid in action; and the operator must have waited sufficiently long in the dark room for the eyes to have become accommodated. A screen examination gave incomparably better information than a bad film. In radiograms the earliest evidence of tuberculosis in the lungs was found not at the apex, but in the outer part of the highest lobe, below the clavicle. In children the apices of the lower lobes might be first involved. The opacities seen were not dense shadows, but were faint steamy areas, usually arranged in a small group. An extremely small degree of movement was sufficient to obliterate them from the film or to cause them to be unrecognisable. Hence a single flash film was far superior to a time-exposed film of any kind. There was some difficulty in recognising early deposits in the deeper part of the lung. It had been said that a tubercle must be 4 mm. in diameter to cast a recognisable shadow, but the speaker was convinced that before the granulomatous nodules had reached anything like this size they must have caused localised disturbance of the vascular and lymph flow. Probably, therefore, in early cases at least, the shadows seen might be due not so much to actual tubercles as to minute congested vessels or to bronchioles and alveoli filled with exudation and débris; in other words, that the tuberculous element was less responsible for the shadows than the broncho-pneumonic. The speaker believed that the question of mediastinitis in children had never received the consideration it merited. He thought it probable that inflammatory attacks with swelling and some degree of inflammation short of actual suppuration might affect the hilus or mediastinal glands in the same way that the cervical glands were so often affected, and he suggested that this might give the clue to many of the obscure chest illnesses of childhood. On the controversial question of hilar tuberculosis, he said that although he believed cases might occur they were extremely rare. In the many cases he had seen with root areas involved the lung tissues were always involved as well. An imperfect film would show opacities at the roots which might erroneously be called hilar tuberculosis, and a very slight degree of movement in a case where both roots and lung were involved might cause obliteration of minute lung opacities, whilst the hilar shadows remained. He had recently made the observation that it was possible when screening to determine whether the root shadows were fluid or solid by screwing down the diaphragm to an area of 3 in. by 2 in. and getting the patient to breathe from full inspiration to full expiration and then back to full inspiration. Solid bodies, such as calcified glands, retained their shape; fibrotic areas showed up at full inspiration like the fine branches of a moving tree; caseated areas resembled crows' nests in tree branches; while fluid areas, such as the large veins, underwent a change of shape which was amœboid in type. There was one point connected with the lungs to which he had never seen a reference. This was the movement in the lungs associated with the alterations in the shape of the pulsating heart. It was greatest in the neighbourhood of the pericardium and about the aorta and pulmonary artery, but could be detected for a considerable distance in the lung. It was this movement he believed which was chiefly responsible for the blurring of the bronchial area shadows which were so common with a time exposure.

On the conclusion of his paper Dr. Lynham showed a large number of X ray films and slides illustrating the various points discussed.

The opening paper on Friday, the 3rd, was given by Dr. R. C. Matson, National Tuberculosis Association, America, whose subject was the

End-Results and Limitations of Artificial Pneumothorax,

and the rôle of other collapse procedures in the treatment of pulmonary tuberculosis. The speaker pointed out that, apart from social and environmental factors, the end-result depended, first, upon the type of disease; secondly, upon the character of the pneumothorax; and, thirdly, and least important, the condition of the opposite lung. The largest proportion of satisfactory collapse cases, as well as the best results in the entire series of over 800 cases, were obtained in the clinical Group I., suggesting that pneumothorax treatment should be instituted before the disease had progressed to the formation of cavities and at a time when adhesions were less likely to prevent a satisfactory collapse. Tables of comparative results obtained in each of five clinical groups where satisfactory collapse, partial collapse, and no collapse was effected, showed unmistakably the value of artificial pneumothorax in all stages of the disease. In no class of case was a satisfactory collapse so vital as in acute phthisis, a partial collapse here being of much less value than in any other form of the disease. Caseation was, in the speaker's opinion, not a contra-indication for pneumothorax, although in cases of progressive caseation, with grave toxæmia and a bad general condition the procedure was of doubtful value. Bilateral cavernous phthisis had always been considered a contra-indication for artificial pneumothorax, but by withholding the treatment until activity in the contralateral lung had largely subsided, and by gradually bringing about the collapse (consisting in many cases of only a thin layer of gas between the lung and the chest wall), a considerable degree of success was attained. Dr. Matson emphasised the paramount importance of obtaining a good collapse where this was possible. In many cases of partial collapse he was satisfied that pneumothorax should be abandoned and other operative collapse procedures instituted, thus giving a 40 or 50 per cent. chance of recovery instead of a less than 20 per cent. one, which was the best result that could be obtained from a partial collapse. His experiences had convinced him that the danger that disease in the contralateral lung would be reactivated by a pneumothorax on the opposite side was exaggerated, and that improvement in the contralateral lung was often coincident with and actually dependent upon improvement of the pneumothorax side. He deprecated the widespread impressions that pneumothorax treatment should be withheld until after a thorough trial of sanatorium methods, and that it should be undertaken with much forethought because of the danger of complications. Of 394 cases under pneumothorax treatment less than 2 per cent. had died as the result of complications directly or indirectly due to the treatment.

Of other operative collapse procedures only four were in general use: extrapleural thoracoplasty; phrenic resection or exairesis; intrapleural pneumolysis; and extrapleural pneumolysis with fills. In the first of these the methods of Brauer and Sauerbruch had undergone so many modifications that at present no great difference existed between them. The speaker emphasised the great importance of removing the ribs close to the spine, since upon this depended largely the degree of collapse obtained. The operation, which was best done under local anæsthesia, should always, he thought, be performed in two stages, which greatly lessened the operative mortality. The patient's fate depended also largely upon the after-care given. The most important point in this connexion, where there was much sputum, was to give sufficient opiate to relieve the pain of coughing and then to encourage the patient to cough and drain the lungs of sputum about every four hours. The results of a good thoracoplasty in properly selected cases showed about the same percentage of recovery as a satisfactory pneumothorax, but the danger of complications in the former was very much greater, especially as regarded the dissemination or reactivation of disease in the opposite lung. Phrenicoexairesis gave only relative rest to the lung, and that only to the lower lobe; hence it was useless if the upper lobe alone were diseased. It was valuable chiefly in conjunction with other procedures, such as a pneumothorax or a thoracoplasty. The operation was not without danger and should be attempted by no one who had not a thorough knowledge of the topography of the parts. Extrapleural pneumolysis was probably of limited value, chiefly because there was no satisfactory substance to use as a fill. Its action, moreover, was purely local. Intrapleural pneumolysis with the burning of adhesions was sometimes of great value, especially with the new Unverricht thoracoscope which was a great improvement on the old Jacobaeus instrument.

Dr. Matson's paper was followed by an interesting discussion in which Mr. Morriston Davies and others took part.

Mr. Harry Platt (Manchester) then spoke on

Forms of Arthritis Simulating Tuberculosis.

He emphasised the difficulties which often rendered the early diagnosis of tuberculous arthritis a matter of uncertainty. Even after a careful clinical review of the symptoms and signs, radioscopic examination and the carrying out of accepted pathological tests, it was frequently necessary to give a non-committal opinion and to insist on a further period of clinical observation. The whole question was to some extent influenced by the vague recognition of what the French observers had called "rheumatisme tuberculeux." Although this conception had been presented some 25 years ago it had received little support in Great Britain. Mr. Platt had found no conclusive evidence in favour of the acceptance of tuberculous rheumatism as a clinical or pathological entity. In dealing with chronic joint affections as a whole it was important to recognise that a joint tended to react to the stimulus of a noxious agent along certain conventional lines. It was true that in tuberculous arthritis they were dealing with a definite specific granuloma involving synovial membrane or bone-marrow, but the entire lesion might progress slowly and be comparatively latent. The reaction of the joint to the presence of the granulomatous growth might then simulate other non-tuberculous affections. It was convenient to consider the various common forms of arthritis which simulated tuberculosis at three age-periods: childhood (up to 14), adolescence (14 to 18), and adult life. In childhood the hip-joint could be taken as illustrating the problem of diagnosis. The conditions which gave rise to difficulties were: pseudo-coxalgia; traumatic arthritis, seen in one stage of coxa vara; infective arthritis; extra-articular osseous foci whether of pyogenic or tuberculous origin. In all these forms there might be the clinical picture of a mild hip disease. In the knee-joint the diagnostic difficulties were concerned chiefly with traumatic synovitis and infective synovitis. In adolescence and in adult life infective arthritis often simulated tuberculosis. Operative exploration in knee-joint conditions was often the most valuable diagnostic measure. In general, after a short period of observation, it was usually possible to give a definite diagnosis, but until this stage was reached it was wise to treat suspected cases on anti-tuberculosis lines.

At the afternoon session Sir Henry Gauvain spoke on the present position of

Light Treatment in Surgical Tuberculosis.

He drew attention to the fact that no one who had taken up this treatment had ever abandoned its use—a striking tribute to its efficacy. Many, however, exaggerated its value, regarding it as a cure-all. Light treatment was simply an aid to conservative treatment; it was not specific; it had its dangers, and there were certain cases which probably should not be subjected to it at all. The speaker dwelt first on the tonic effects of the sun upon the mind. At Alton efforts had recently been made to measure this stimulation by subjecting defective and other children to intelligence tests, both group and individual. It was found that the intelligence was raised, on an average, 10 per cent. above that normally shown in any given case. The effects on the body were both local or direct, and remote or indirect. Ultra-violet light had a bactericidal effect on the blood but had very little penetrating power. Penetration could be increased by certain methods—e.g., by exsanguinating a part as was done in lupus by the Finsen light. Pigmentation varied greatly in different individuals. He believed it was a good thing because it protected a patient, who would therefore be able to stand longer exposures and greater degrees of heat and cold. It had also probably a definite prognostic value. Light treatment had no effect on diphtheritic rhinitis or on diphtheritic throats. How the remote or indirect effects of light were produced was not known. The bactericidal power of the blood appeared sometimes to be lowered instead of being raised by the treatment, and he urged that in elderly subjects the bactericidal power of the blood should be tested before and after exposures, so that the treatment might be discontinued where it was found unsuitable. No other artificial light treatment could compare with the Finsen lamp in lupus. The artificial light most nearly approximating to sunlight was the carbon-arc lamp. All types of lamps were used at Alton, each having its own indication.

The last paper of the session was given by Prof. Louis Cobbett, his subject being the

Resistance of Civilised Man to Tuberculosis: Is it Racial or Individual in Origin?

He began by drawing attention to the fact that the diseases of civilised lands ran riot when introduced among isolated and primitive peoples, the converse also being true. People were more resistant to the attack of the infectious diseases of their own countries and districts than to those of foreign diseases with which neither they nor their ancestors had come into contact. The causes of this universal resistance to indigenous diseases he believed to be two-fold: racial immunisation and acclimatisation. By the first should be understood a slow growth of the resisting power of the people which rose by slow degrees, being transmitted by inheritance and developing in accordance with the law of adaptation to environment. By acclimatisation he meant a process which concerned only the individual, not transmitted by inheritance and independent of the history of the race. It was probably really a process of unconscious immunisation, brought about by receiving repeatedly doses of the specific micro-organism too small to cause recognised disease. Acclimatisation did not depend upon race, since members of the same race might be resistant and others susceptible, according to the personal experience of each. A further proof that such resistance or immunity as was implied in the term acclimatisation was not racial was the fact that it was easily lost by residence in a country where the disease was not met with. The speaker gave instances of this, as well as of facts establishing the possibility of acquiring a high degree of resistance to certain infective diseases—e.g., diphtheria—by living in an environment where the diseases were prevalent. On the question of how to distinguish between a resistance of a people which had been acquired ab initio by each individual and one which was the result of causes acting on preceding generations, Prof. Cobbett suggested that the crucial test was its permanence. Individual immunity would disappear in a generation if the people were removed from the infected environment. The point was difficult to prove conclusively in the nature of the case, but when all the circumstances were duly weighed it appeared to him that there was an innate susceptibility to tuberculosis in various races, notably Indian, Negro, and Chinese, which was far greater than that of the white races in the United States, and greater than could possibly be accounted for by purely environmental factors. The speaker concluded that racial resistance and racial susceptibility were real, and were due to hereditary factors deeply fixed in the blood of each race. Superimposed, so to speak, on this high or low resisting power in every place in which the people were brought into contact with the tubercle bacillus was an immunity of the individual. Both racial resistance and individual immunisation played a part in determining the reaction of the people to tuberculosis, and neither factor could safely be disregarded.

On Saturday, the 4th, there was a demonstration of a number of pathological specimens by Prof. Cobbett.

The conference concluded by a visit to the East Anglian Sanatoria, by the kind invitation of Dr. Jane Walker, all the visitors being greatly impressed by what they saw of the extent and character of the work carried on.

The Services.

ROYAL ARMY MEDICAL CORPS.

ARMY RESERVE OF OFFICERS.

Army Dental Corps.—Lt. P. Colk, from Green Howards, Res. of Off., to be Lt.

TERRITORIAL ARMY.

Lt.-Col. (Bt. Col.) C. R. White, from R.A.M.C., T.A., to be Col., and Assistant Director of Med. Services, 53rd (Welsh) Div., vice Col. H. T. Samuel, vacated on completion of tenure of appointment.

Maj. F. T. Rees to be Lt.-Col. and to command 53rd (3rd Western) Casualty Clearing Station.

Capt. A. A. Finnigan (late unattached List O.T.C.) to be Lt., and relinquishes the rank of Capt.

Lt. E. B. Murrell (late R.F.A., S.R.) to be Lt.

A. M. Robertson to be Lt.

DEATHS IN THE SERVICES.

Surgeon-Major Arthur Edwin Temple Longhurst, who retired from the medical department of the army in 1875 on half-pay, and who died recently at the age of 93, was a veteran of the Crimea and Indian Mutiny. Born at Kirby Mallory, Leicestershire, in 1831, he qualified with the M.R.C.S. Eng. and L.S.A. in 1853, and after acting as house surgeon at the Loughborough Infirmary and Dispensary joined the medical department of the army. Later he graduated at St. Andrews University. In the Crimea he was at the Siege of Sebastopol and for his services received the medal and clasp and the Turkish medal. While stationed with Florence Nightingale in the hospital at Scutari he formed with her a friendship which endured till her death. During the Indian Mutiny he was at the attack on Jugdeespore, was mentioned in despatches, and received the medal. From 1861 to 1865 he was personal surgeon to General Sir Hugh Rose, Commander-in-Chief in India, and retired in 1876. After his retirement from the army he took up medical practice in Belgravia.

Correspondence.

"Audi alteram partem."

RADIUM EMANATION.

To the Editor of The Lancet.

Sir,—The report in the lay press of the speech of the chairman of governors of Middlesex Hospital is destined to convey the impression that the Middlesex Hospital is responsible for what is undoubtedly a step in the real progress of radium therapeutics.

The remarks made by Mr. S. A. Courtauld when presiding at the annual court of governors have been made without a due appreciation of, and without sufficient knowledge of, what has been done in other centres, and more especially in Manchester. For the past ten years the Manchester and District Radium Institute has been harnessing the gas given off by radium in solution (originally called "emanation" by Sir Ernest Rutherford and "niton" by the late Sir William Ramsay, and now for some inexplicable reason called "radon"), and sealing it up in tubes for use at the hospital, or for distribution among the eight participating hospitals included in the original scheme of the Manchester and District Radium Institute.

Not only so, but "seeds" containing the emanation gas have been in constant and daily use during the past six years. The authorities of the Manchester and District Radium Institute have, however, definitely declined to send tubes, spicules, or seeds haphazard over the country, realising that radium or its emanation gas is too dangerous a material to place in the hands of all and sundry. Realising also the many risks inherent in its possibly indiscriminate employment by those not fully conversant with its radio-active properties, they have very rightly insisted that any radium or radium emanation sent out from the Institute shall only be used on the advice and under the supervision of the radiologist to the Institute.

The methods of harnessing or bottling radium detailed in the report, and described as if they were new and original, are practically identical with the methods which have been in daily use at the Manchester and District Radium Institute for the past ten years, the emanation plant, liquid air pump, &c., being confined in a specially built room lined with thick sheet lead and having a "safe" door weighing over two tons.

Middlesex Hospital authorities have been fortunate in obtaining on loan a considerable supply of radium from the original war stock held by the Government, but, even allowing for this, their own stock can be little larger than that held by the Manchester and District Radium Institute and paid for by the generosity of Manchester citizens.

We feel that, unwittingly no doubt, the report of this speech will convey the impression that the Manchester and District Radium Institute is behind the times in its scientific arrangements, whereas in reality it has been in the very van of progress from its inception and formation in 1914, as can be demonstrated to anyone sufficiently interested to call at the Institute.

We are, Sir, yours faithfully,

Arthur Burrows,
Radiologist.
W. Milligan,
Hon. Secretary and Treasurer.

Manchester and District Radium Institute, Nelson-street,
Manchester, April 3rd, 1925.

To the Editor of The Lancet.

Sir,—In reply to the letter of Capt. Hayward Pinch in your issue of April 4th, under this heading, the Radium Committee of the Middlesex Hospital do not hold themselves responsible for certain unjustifiable claims which have appeared in the press respecting the new Radon Centre at the Middlesex Hospital. This centre has been established at the request of the Medical Research Council, and with the financial support of the British Empire Cancer Campaign, to enable a wider research to be made into the uses of radium emanation. The services of the new installation will not be restricted to the Middlesex Hospital, but will be available for certain other hospitals.

The Middlesex Hospital has always recognised the valuable pioneer work of other centres in the use of emanation in this country, and has already in the lay press disclaimed priority in this field.

I am, Sir, yours faithfully,
W. SAMPSON HANDLEY,
Chairman of the Radium Committee of the
April 6th, 1925. Middlesex Hospital.

TUBERCULIN DISPENSARIES.

To the Editor of THE LANCET.

SIR,—In your issue of March 7th last there appeared a letter from Dr. Annie McCall under this heading. I have looked, in succeeding issues, for other letters called forth by this one, as there is a sort of challenge in it as to the relative value of tuberculin treatment. In former days there would have been many. Why are there none now? Does it mean that by the majority tuberculin has been relegated to the limbo of forgotten and useless remedies? Or does it mean that tuberculin has achieved an unchallenged place in therapeutics? I fancy that the former is the true explanation. Yet if Dr. McCall's figures are supported by evidence they are surely a striking proof of the high value of tuberculin treatment.

Dr. McCall only states that she is told that there is this evidence, and one would be glad to learn the original facts on which her statement is based. I, for one, after having treated several hundreds of patients with tuberculin in an experience dating back to 1910, when I first learnt to use tuberculin at Victoria Park Hospital (under the late Dr. George Heron, who claimed to be the first to use it in this country, having studied under Koch and who persisted in its use right through the time of its darkest days), am prepared to accept her figures, as I believe in the efficacy of tuberculin. I believe from experience that there are only three remedies of proved sovereign value for the treatment of pulmonary tuberculosis. They are: Hygienic living as learnt in a sanatorium, rest, and tuberculin. Why, then, is tuberculin not used far more than at present? I believe because in many hands good results have not been obtained, and in some cases bad results have followed its use; and that there are two causes for this—viz., (1) wrong comprehension of the action and use of tuberculin, and (2) inexperience of its use.

With regard to wrong comprehension, there arose a theory, fatal in my opinion to the success of tuberculin therapy, that the object of the treatment was to increase the dose to the highest quantity possible in order to achieve the highest immunity to tuberculin and thereby nullify the disease of tuberculosis. To this end systems of progressive dosage were introduced. At first simple arithmetical progressions were advocated, then more complicated geometrical progressions, until suggestions of harmonic progressions caused the whole method to die of its own complications. After all, what result could these meticulous methods procure? They could, in many cases, procure a high immunity to tuberculin, and I can remember cases which had achieved a condition of standing big doses of tuberculin without noticeable effect and yet steadily and finally dying of phthisis. Naturally a practice capable of producing such results fell into disrepute; and the theory must fall to pieces, the fact being that immunity to tuberculin does not cure tuberculosis.

Inexperience as a cause of poor or bad results needs little comment except to say that tuberculin is a potent drug capable of doing much harm in inexperienced hands, as are all other potent drugs. How, then, are the notable successes claimed by certain observers to be explained? The successes may be thought not to have been achieved, or may be considered to be only those which would occur without the use of tuberculin. As a believer in the use of tuberculin, I leave this explanation as it stands.

My own explanation is as follows: There seems to me to be only one classification of cases of pulmonary tuberculosis useful for considering the value of treatment. (1) Those, the vast majority, who cure themselves; (2) those in whom, unaided, the issue is doubtful; (3) those who are inevitably overwhelmed. These classes, of course, shade off into each other.

It is obvious that in class (1) the natural forces of the patient fight down the germ by tissue and serum reaction to the germ. I believe that tuberculin has the power to stimulate these curative reactions (fibrosis, &c.) to tubercles as distinct from its power to stimulate the production (by tuberculin reactions) of antibodies to tuberculin which is the product of the tubercles. So alcohol may produce acute reactions (drunkenness) or chronic tissue reactions—e.g., neuritis—or arsenic may give acute reactions (gastro-intestinal irritation) or chronic tissue reactions (skin cancer). In fact, I believe it to be less likely that tissue reactions will occur if acute "tuberculin reactions" are produced than if subreactive doses are given, just as the steady soaker is more likely to get neuritis than he who gets drunk once a week but requires increasing quantities to do so.

On my theory, then, the treatment of tuberculosis by tuberculin consists in giving tuberculin with the object of stimulating tissue reaction to tubercles. The practice of this is not one to be undertaken lightly by the inexperienced. On the contrary, it requires much clinical experience and watching of cases over long periods; and the greater the experience the greater the successes. There is no rule-of-thumb method. Each dose must be prepared *after* consultation with the patient, and not *before* from mathematical tables, and will vary with the findings at the consultation. The human body is not a test-tube and its functions are too numerous and too vastly complicated to be reduced to any mathematical formula. But, fortunately, though experiments are fallacious, experience is frequently a trusty guide, and I believe that those who have most experience with the use (not abuse) of tuberculin will be the most successful doctors for tuberculous patients.

I am, Sir, yours faithfully,
W. O. PITT, M.D., D.P.H.,
Late T.O., Essex County Council, &c.
Worthing, March 29th, 1925.

THE MALARIAL TREATMENT OF GENERAL PARALYSIS OF THE INSANE.

To the Editor of THE LANCET.

SIR,—The letter of Dr. J. D. Silverston published in your issue of April 4th draws attention to a very useful method of transmitting malarial blood from place to place, and I should like to add my own experience of a somewhat similar method. When I began to use cooled blood, precisely a year ago, on April 4th, 1924, I was unaware of Pötzl's method, described by Dr. Silverston, hence the technique I employ differs from that given by this writer.

The method used at Claybury Mental Hospital to defibrinate the blood is as follows. Immediately upon withdrawal from a vein, the blood is placed in a sterile test-tube and stirred with a sterile glass rod. The fibrin collects on the rod. Sometimes, having collected on the rod, the fibrin slips off. In this case the rod will, of course, be found to be quite free from threads, whereas if only a small amount of fibrin has collected the rod will show a slightly roughened appearance. Provided the fibrin has not fallen off the rod, the latter, at the termination of the stirring of 15–20 c.cm. of blood, should have a thick coating of fibrin around it. In any case, the stirring should be continued for five minutes. Defibrination being complete, the red cells may then be injected into the patient to be treated. Since August, 1923, when I commenced using this method, about 70 cases have been successfully inoculated with benign tertian malaria.

When it is desired to delay inoculation for any great length of time the following procedure is used at Claybury Mental Hospital. The defibrinated blood is cooled to a low temperature and the tube packed in sawdust. I have found that it is unnecessary to freeze the blood completely provided the temperature is lowered to a few degrees above 0° C. If there is a small quantity of blood to be cooled, say 5–10 c.cm., the process may be managed on a freezing microtome, such as a Cathcart. The platform should be removed so that the ether plays directly upon the walls of the test-tube, the latter being held in the situation of the platform. With large quantities of blood the microtome is less suitable.

Using the above method blood has been sent from the address below to Colchester, Birmingham, Warwick, and Exeter (170 miles). In most instances the blood was sent in the usual way through the post as a pathological specimen. The inoculations have been successful. I am, Sir, yours faithfully,

G. DE M. RUDOLF.

Claybury Mental Hospital, Essex, April 4th, 1925.

TREATMENT OF ANOREXIA IN CHILDREN.

To the Editor of THE LANCET.

SIR,—I have read with great interest Dr. Neill Hobhouse's article on this subject published in THE LANCET of March 7th, and take the liberty of suggesting that when considering the case of children refusing solid food, he omits to call attention of the reader to a possibility which may account for the fact. Several cases under my care between the ages of 3 and 5 have shown a distinct distaste for solid food, though at the same time they never complained of sore-throat, and the mothers had never suspected that enlarged tonsils were the cause of the trouble, nor was this perceived until after careful examination. Although infective tonsils are to be considered a source of infection of the stomach which tend to upset the ordinary function of appetite, the crux of the problem may lie chiefly in the *mechanical* obstruction to which they give rise.

I am, Sir, yours faithfully,

Rome, March 26th, 1925. WALTER BENZIMRA.

PETERBOROUGH WAR MEMORIAL HOSPITAL.—The Peterborough Hospital Committee is about to begin the erection of a war memorial hospital to cost £70,000.

ITALIAN SPAS.—The Italian State Tourist Department (known as the E.N.I.T.) is again organising an international visit of doctors to Italian health resorts to take place from Sept. 5th to Sept. 21st next. Among the places to be visited are S. Pellegrino, Fonte Bracca, Acqui, Alassio, San Remo, Ospedaletti, Bordighera, Pietra Ligure, Nervi, Rapallo, Santa Margherita, Portofino, Viareggio, Montecatini, Monsummano, Chianciano, and Fiuggi. At each place a conference will be held, and each member of the tour will receive a copy of the proceedings in his native language. A first-class special train will be provided, and the members will be accommodated at the best hotels. The party will be limited to 200 persons, and a certain number of places will be reserved for members of the families of the doctors. The fixed charge for the tour, including cost of travel, railway, and hotel expenses in Italy, will be lire 1600 (about £15). Members will be granted reduced rate tickets from the Italian frontier to Milan and from Rome back to the frontier. Full particulars and application forms may be obtained from the Travel and Tourist Office of the E.N.I.T., 12, Waterloo-place, Regent-street, London, S.W. 1.

THE BATEMAN APPEAL.

As already explained in THE LANCET, it has been felt that material assistance ought to be offered to Dr. Bateman to meet the legal expenses of his recent successful appeal against conviction and to make good the deficiency in his professional income. Accordingly, the Bateman Fund has been opened and lists of contributions have appeared in recent issues. We have received additional contributions as follows:—

	£	*s.*	*d.*
Already received and acknowledged ..	426	4	0
Dr. R. Adams Brewis	1	1	0
Dr. G. N. Campey	1	1	0
Dr. W. T. Hillier	1	1	0
Dr. B. S. Robson	1	1	0
Anonymously	0	10	6
Dr .W. E. McEwan	0	10	0

Remittances should be forwarded to the Manager of THE LANCET, 423, Strand, W.C. 2, and made payable to the "Bateman Fund Account."

Parliamentary Intelligence.

HOUSE OF COMMONS.

WEDNESDAY, APRIL 1ST.

Neurasthenic Patients at Saltash.

Colonel **DAY** asked the Minister of Pensions whether he was aware that during the past 14 months some 370 men had taken their discharge from the Ministry institution for neurasthenics; how many were discharged at their own request; what were the principal reasons given for desiring discharge; whether he was aware that some of the men were more than 350 miles from their homes; and if he could arrange for men from Scotland, Ireland, and the North of England to be placed in an institution nearer their homes.—Major G. C. **TRYON** replied: The hon. and gallant Member refers, I presume, to the Ministry Institution at Saltash. During the past 14 months 310 patients (not 370 as stated in the question) have been discharged from this institution. Of these, 171 either discharged themselves contrary to medical advice, or did not return from the leave that had been granted them. No record is kept of the reasons for the discharge in the latter cases, but I am advised that they are ordinarily accounted for by the mental instability and restlessness associated with the condition for which they are receiving treatment. It is the policy of the Ministry as far as possible, and subject to medical requirements, to treat neurasthenic cases in institutions near their homes, and in fact out of 791 cases of neurasthenia under treatment from each of the portions of the kingdom referred to in the question the great majority are in institutions in those parts, and only 37 are at Saltash.

Convictions for Drunkenness.

Mr. **GROVES** asked the Home Secretary the number of convictions for drunkenness, male and female, in the metropolitan police district for the calendar years 1923 and 1924.—Sir W. **JOYNSON-HICKS** replied: The total for the metropolitan police district of the figures given in Table VI. of the licensing statistics for 1923 is 23,414 males and 6610 females. The total which it is expected the volume for 1924, now in preparation, will show is 23,512 males and 6536 females.

Progress of House Building.

Mr. **MACKENZIE LIVINGSTONE** asked the Minister of Health how many houses had been completed under the Chamberlain and Wheatley Acts respectively; how far this number was supplying the normal increase of the population; and how far it was overtaking the existing shortage of houses.—Sir **KINGSLEY WOOD** (Parliamentary Secretary to the Ministry of Health) replied: Up to March 1st last the number of houses completed in England and Wales under the Housing Acts of 1923 and 1924 was: Act of 1923, 64,249; Act of 1924, 1285; total, 65,534. Considerable numbers of additional houses are being erected without State subsidy. During the 12 months ending on Sept. 30th last the total number of houses completed with and without subsidy was approximately 110,000, and my right hon. friend would expect this number to be exceeded during the current 12 months if present conditions continue. In answer to the second and third questions, I can only say that on the present rate of construction house building is, in the opinion of my right hon. friend, providing for the normal increase of population, and also making progress in overtaking arrears.

Clearance of Slum Areas.

Mr. FENBY asked the Minister of Health what steps, if any, were being taken to clear slum areas; and how many schemes had been started for this purpose since Nov. 1st, 1924.—Sir KINGSLEY WOOD replied: Since Jan. 1st, 1919, 69 slum schemes in various parts of the country have been confirmed, and further schemes are under consideration or in course of preparation. The number confirmed since Nov. 1st last is 11. Up to the end of January last part or the whole of the areas had been acquired in the case of 27 schemes, and clearance was in progress, or had been completed, in the case of 16 schemes. The only other information that is available is that 2145 dwellings for rehousing persons displaced from slum areas had been definitely arranged for at the end of January.

THURSDAY, APRIL 2ND.

Approved Societies and Hospital Contributions.

Mr. TINNE asked the Minister of Health whether he was aware of the large unspent accumulated health insurance funds; and, having regard to the unremunerative services rendered by voluntary hospitals to insured persons, would he bring influence to bear upon the approved societies to make suitable contributions out of this surplus to the funds of voluntary hospitals treating insured persons.—Mr. N. CHAMBERLAIN replied: The answer to the first part of the question is in the affirmative. The answer to the second part is that for some time considerable sums have been paid yearly by societies to voluntary hospitals out of disposable surplus, and I hope these sums may be increased in the future. The matter is, however, primarily one for consideration by societies, though it will no doubt, with other similar questions, be reviewed by the Royal Commission on National Health Insurance now sitting.

Safeguarding Act and X Ray Apparatus.

Dr. LITTLE asked the President of the Board of Trade whether he was aware of the effect of the Safeguarding of Industries Act on X ray workers in this country; that, in some cases, the actual tax which the consumer had to pay, owing to various accessory charges, might be as high as 60 per cent.; that apparatus which was not being manufactured in this country had this duty charged upon it; and whether, seeing that this made it difficult for medical men practising X ray treatment to have the best modern apparatus, he would consider the advisability of removing from the schedule at any rate those types of apparatus which were not manufactured in this country by British firms.—Sir BURTON CHADWICK (Parliamentary Secretary to the Board of Trade) replied: I am unable to conceive how the actual tax paid under the Safeguarding of Industries Act can possibly be at the rate suggested by the hon. Member. I am aware that certain special types of X ray apparatus are not at present produced in this country, but having regard to the purpose of the Act in question, I am not prepared to introduce the legislation necessary to give effect to the hon. Member's suggestion.

Health Insurance Benefits.

Mr. VIANT asked the Minister of Health whether, on the cancellation of their present scheme of additional benefits under the National Health Insurance Acts as from July 5th, 1925, it would be possible for an approved society to transfer the balances on account in respect of non-cash benefits funds remaining at the expiration of their existing schemes to a special assistance benefit fund for the provision of similar non-cash benefits to new entrants or, alternatively, to persons admitted as members in the interval between the date of valuation, Dec. 31st, 1922, and the date of the coming into operation of the new scheme on July 6th, 1925.—Mr. N. CHAMBERLAIN replied: The balances in question can only be applied in supplement of sums available for distribution under a new scheme of additional benefits to members qualified to receive them in accordance with the Act and Regulations. A scheme cannot provide for the utilisation of this money for the provision of non-cash benefits to new entrants from the date of their becoming members, but I may point out that persons admitted as members in the years 1923, 1924, and 1925 will be entitled to participate in the benefits provided under the new schemes at varying dates according to the duration of their membership.

Medical Officers of Health and Housing Shortage.

Lieut.-Colonel FREMANTLE asked the Minister of Health if he would arrange that medical officers of health, in their forthcoming and future annual reports, should state whether or not there was, in their opinion, a shortage of housing available for the working classes in the several parts of their districts; and whether he would define the standard of shortage for the purpose of such report.—Mr. N. CHAMBERLAIN replied: I will give careful consideration to my hon. and gallant friend's suggestion, but I doubt whether it is practicable to define such a standard as is contemplated for general application.

Antitoxin for Scarlet Fever.

Lieut.-Colonel FREMANTLE asked the Minister of Health if his department and the Medical Research Council have now sufficiently examined the efficacy of the toxin and antitoxin for test, prevention, and cure of scarlet fever, as officially used in several of the United States of America; and with what result.—Mr. N. CHAMBERLAIN replied: Investigations are being actively pursued in my department and by the Medical Research Council, and the results will be published from time to time as knowledge is gained. I am advised that these investigations entail prolonged laboratory and clinical observations before a confident statement of the efficacy of these several procedures can be made on the strength of their trials in this country.

The Spahlinger Treatment.

Mr. THOMAS WILLIAMS asked the Minister of Health what steps, if any, he had taken to secure a supply of the Spahlinger treatment for tuberculosis sanatoria in this country; and whether he would give financial assistance to any local authority who obtained a supply of this serum for the use in their institutions.—Mr. N. CHAMBERLAIN replied: As regards the first part of the question, I may say that all practicable steps have been taken by my department to secure a supply of M. Spahlinger's preparations for scientific investigations, and I regret that I am still without information as to when such a supply will be available in this country. As regards the second part of the question this will be considered if and when it arises.

Small-pox Outbreak at Kettering.

Sir MERVYN MANNINGHAM-BULLER asked the Minister of Health if he could give the number of cases of small-pox due to the outbreak in Kettering, and the percentage of the persons thus affected who had been vaccinated.—Mr. N. CHAMBERLAIN replied: Up to March 30th 71 cases of small-pox were notified in the urban district of Kettering and seven in the rural district. Of the total of 78 patients the vaccinal condition of one was doubtful, 11, or 41·1 per cent., were stated to have been vaccinated in infancy, and one at 5 years old. It should be stated that none of these vaccinated patients had been re-vaccinated, and, all of them, with the exception of one patient aged 25, were over 39 years of age.

External Examinations at London University.

Mr. HARRIS asked the President of the Board of Education whether any formal communication had passed between Lord Ernle, the late chairman of the Departmental Committee on the Constitution of the University of London, and the Chairman of the Convocation of the University with regard to the future of the external side of the University; and, if so, what was the nature of such communication.—Lord E. PERCY replied: The late chairman of the Departmental Committee addressed a letter to the Chairman of Convocation on Jan. 27th last inviting Convocation to give evidence before the committee. In the course of that letter it was stated that the committee hoped that Convocation would not undertake the labour of preparing and giving evidence on the general question of the continuance of the external examinations conducted by the University, because in the view of the whole committee those examinations had in the past served, and would in the future serve, a useful purpose.

Proposed Legalising of Hospital Tombolas.

Colonel Sir ARTHUR HOLBROOK asked the Home Secretary if he was aware that hospital tombolas, which had been the means of raising several hundred pounds to promote the work of hospitals, had been repressed by the police authorities; and whether he would consider the issue of regulations that these voluntary efforts to assist hospitals should not be discouraged.—Sir W. JOYNSON-HICKS replied: I have no authority to issue instructions which would have the effect of exempting offenders of a particular class from the penalties prescribed by law.

Scheduling of Cannabis Indica.

Mr. FORREST asked the Home Secretary whether he was aware that, in consequence of the scheduling of cannabis indica as a poison, all firms using it, even for minor manufactures of a non-deleterious nature, had had only from Feb. 26th to April 3rd to label millions of articles; and whether, in view of the impossibility of conforming within this time with the regulations, he would postpone the date of their enforcement and in the meantime investigate the need for their existence in these specific cases.—Sir W. JOYNSON-HICKS replied: I am afraid there is no power to postpone the operation of this Order. Under the statute the resolution of the Council of the Pharmaceutical Society for the inclusion of a substance in the Poisons Schedule takes effect one month after the Order of the Privy Council Office approving it has been advertised in the *London Gazette*. As the resolution was passed as long ago as last August, ample notice has been given to all interested parties; and there do not appear to be any grounds on which the Government could properly intervene now. I am sure that no harsh measures will be taken by the Pharmaceutical Society in the enforcement of the law.

MONDAY, APRIL 6TH.

Pay of Indian Army Medical Officers.

Brigadier-General CHARTERIS asked the Under Secretary of State for India whether he was aware that the recent augmentation of pay of British officers in India, both of the British Army and of the Indian Army, applied to all officers except those of the Royal Army Medical Corps, the Indian Medical Service, Army Dental Corps, and the Royal Army Veterinary Corps; that this was certain to prejudice future recruitments for these essential services in India; and would he state the reason for this decision.—Earl WINTERTON replied: Officers of the Indian Medical Service in military employ have been granted the same pay concession as those in civil employ as a result of the recommendations of the Commission on the Superior Civil Services in India, and the same passage concessions as have recently been granted to officers of the Indian Army. The case of the other services mentioned has been reserved for further consideration as there is a possibility of changes affecting them in the near future.

White Lead Convention.

Mr. GEORGE HARVEY asked the Home Secretary whether His Majesty's Government proposed to give effect, either in whole or in part, and to what extent, to the proposals of the draft convention of the International Labour Conference (Geneva, 1921) as to the use of white lead in painting buildings.—Sir W. JOYNSON-HICKS replied: I am considering the introduction of a Bill to give effect to those proposals in the draft Convention as to which there is general agreement, in order that the agreed regulations for the protection of the workers may be brought into operation as soon as possible.

Insanitary Houses.

Viscountess ASTOR asked the Minister of Health in how many cases objections to notices served by local authorities upon the owners of insanitary property, with a view to houses being put into order, had been raised on appeal to his department; and how many of these appeals have been rejected.—Sir KINGSLEY WOOD replied: During the year ended Dec. 31st, 1923 (the last year for which figures are available), notices requiring repairs, &c., under the Housing Acts were served in respect of 25,277 houses. During this year 37 appeals were received by the department, five appeals were formally dismissed, three allowed, and four allowed in part. The remainder were not proceeded with.

Salaries of Health Ministry's Medical Staff.

Colonel Sir ARTHUR HOLBROOK asked the Minister of Health whether the increase of salary of £50 per annum to be given to full-time medical officers of the Ministry whose services were being retained was in lieu of bonus or gratuity; and, if not so granted, would he explain why it was granted, seeing that the work had been and was steadily diminishing in comparison with that of the past five or six years.—Mr. N. CHAMBERLAIN replied: No such increase of salary as is mentioned in the first part of the question has been granted in my department; the second part does not therefore arise.

Juries at Coroners' Inquests.

Mr. CHARLETON asked the Home Secretary whether his attention had been called to the consistent refusal of certain coroners to empanel a jury at inquests even in serious cases; and whether he would take steps to ensure that, where bereaved relatives or representatives acting on their behalf expressed the desire for the coroner's inquest to be conducted with the aid of a jury, this should be done.—Sir WILLIAM JOYNSON-HICKS replied: The answer to the first question is in the negative. With regard to the second I hope shortly to introduce a Bill which will deal with this and other parts of the law relating to coroners' inquests.

COLLEGE OF PESTOLOGY GOLD MEDAL.—At a luncheon of the College held at Pagani's Restaurant, London, on Monday, March 30th, Sir William Simpson Vice-President, in the chair, Sir Ronald Ross presented the gold medal of the College for the best essay on the prevention of malaria to Mr. C. P. Shute, of 82, Pothes-road, Dorking, Surrey. The prize-winning essay had been selected from those of well over 300 competitors in all parts of the world. Honourable mention was made of four other essays submitted, the writers being Mr. E. H. Black, health officer and chairman to the Mosquito Destruction Board at Kuala Lumpur, F.M.S.; Mr. C. Pearce, city engineer of Gibraltar; Dr. Waugh Scott, and Mr. G. Fox Wilson, of the Royal Horticultural Gardens at Wisley.

Obituary.

ABRAHAM EMRYS JONES, M.D. EDIN., J.P.,

LATE SENIOR SURGEON, MANCHESTER EYE HOSPITAL.

Abraham Emrys Jones, in his time one of the best known ophthalmic surgeons in Manchester, died on March 31st at the age of 73. He was born at Llanarth, Cardiganshire, and received his medical education at the Universities of Glasgow and Edinburgh, graduating M.B., C.M. at the latter in 1875. A year later he took the M.R.C.S. Eng., and became house surgeon at the Royal Eye Hospital, Manchester, and in 1879 was appointed honorary assistant surgeon at that institution, having obtained the M.D. Edin. with commendation in 1877. He devoted his attention to diseases of the eye, and soon acquired a large consulting practice in the city. He held the office of consulting ophthalmic surgeon to the Bolton Infirmary, was honorary oculist to Barnes Home Industrial Schools and the Warehouse and Clerks Schools. He was a J.P. of the city of Manchester and a referee under the Workmen's Compensation Act. He served on the Medical Board of the University of Wales, and also on the University Court. Besides being actively engaged in eye work in hospital and in private practice, his abundant energy found other outlets, including much work done for the Manchester and Salford Sanitary Association, of which he was one of the secretaries for 12 years and president for one year, and he contributed papers on literary subjects to the Manchester Literary Club, of which he was a member. In 1911 he was president of the Manchester Medical Society. He was a clear and effective platform speaker. Several years ago he resigned the active duties as senior surgeon at the Manchester Royal Eye Hospital, and later gradually retired from private practice. Some of his popular lectures were published by the Manchester and Salford Sanitary Association. One of his addresses on the Disposal of the Dead had far-reaching effects; it led to the formation of the Manchester Cremation Society, and the subsequent erection of the Manchester Crematorium, of which he was one of the directors. An enthusiastic Welshman, a lover of music, and deeply interested in all that concerned the interests of Wales and the Welsh, he was a patron and president of the Welsh National Society of Manchester. His remains were cremated at the Manchester Crematorium on April 3rd, the Royal Eye Hospital and the Manchester and Salford Sanitary Association being represented by former colleagues. Dr. Emrys Jones leaves a wife, a son, and a daughter.

Medical News.

UNIVERSITY OF LIVERPOOL.—At examinations held recently the following candidates were successful:—

DIPLOMA IN TROPICAL MEDICINE.

J. Black, E. J. Crawford, Mary W. Ellam, F. N. Green, J. T. Johnson, Elizabeth K. Mackay, K. S. Shah (recommended for A. H. Milne Medal), C. H. B. Thompson, and J. J. de Waal.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.—An extraordinary Comitia was held on April 6th, Sir Humphry Rolleston, the President, being in the chair. He referred to the loss the College had sustained by the recent death of Dr. J. A. Ormerod, the Registrar, and, on the motion of the Second Censor, a resolution expressing condolence with his family and referring to his services in the office of registrar for more than 16 years was passed. The President then delivered the annual Presidential address. He referred to the fact that there are now 373 Fellows as against 91 a hundred years ago, and that the Members now numbered 658, while there was still one Extra-Licentiate. He referred to the work of the College during the past year, mentioning the special alteration of the by-laws, permitting the admission of women to the Fellowship. He then delivered obituary addresses upon the 11 Fellows who died during the presidential year—namely, Dr. Hugh Walsham, Dr. R. Hingston Fox, Sir Sydney Russell-Wells, Dr. Sidney H. C. Martin, Dr. Henry Gervis, Dr. J. F. W. Tatham, Dr.

Herbert Williamson, Dr. Clement Dukes, Sir James Mackenzie, the Rt. Hon. Sir Clifford Allbutt, and Dr. J. A. Ormerod. On the motion of Sir William Church, the Senior Fellow, a hearty vote of thanks was accorded to the President for his address. Sir Humphry Rolleston vacated the presidential chair and the College proceeded to the election of President. Sir Humphry Rolleston obtained 83 votes out of 94 voting, and was re-elected President for the ensuing year. Licences were granted to four candidates, and permission given to seal their diplomas. Communications were received from the Secretary of the Royal College of Surgeons, dated Feb. 13th and March 12th. The meeting was then constituted as a special extraordinary Comitia for the purposes of a report from the Censors' Board. This report having been adopted, the following resolution was passed on the motion of the Senior Censor: "That William Lovell be declared to be no longer a Licentiate of the College; that he forfeit all the rights and privileges of a Licentiate; and that his name be expunged from the List of Licentiates —during the pleasure of the College." The President afterwards dissolved the Comitia.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—At a quarterly meeting of the Council of the College, held on April 2nd, with Sir John Bland-Sutton, President, in the chair, the Jacksonian Prize for 1924, on the pathology, diagnosis, and treatment of œsophageal obstruction, was awarded to Mr. Arthur L. Abel (University College Hospital), surgeon to Kensington General Hospital. A certificate of honourable mention was awarded to Mr. Edward Musgrave Woodman, surgeon, Ear and Throat Department, General Hospital, Birmingham. The subject of the prize for 1926 is the pathology, diagnosis, and treatment of abscess of the brain. Mr. Alexander Primrose, professor of clinical surgery and Dean of the Medical Faculty, University of Toronto, and Mr. John Basil Hall, consulting surgeon, Royal Infirmary, Bradford, and President of the British Medical Association, were elected Fellows of the College under Section 5 of the Charter of 15 Vict., relating to Members of 20 years' standing. The following diplomas were conferred on candidates who have complied with the necessary by-laws:—*M.R.C.S.:* Thomas S. Donovan (Birm.) and Clifford James (Middlesex Hosp.). *L.D.S.:* Joseph H. Adler (Charing Cross and Royal Dental Hosps.).

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—There will be an intensive course in medicine, surgery and the special departments beginning on Monday, April 20th, at the Hampstead General Hospital. Daily sessions will be held from 10.30 until late afternoon, comprising clinical demonstrations, clinics, operations, and exhibitions of cases. A course of proctology will be held at St. Mark's Hospital from April 20th to May 2nd. Members of the staff will perform operations followed by lecture-demonstrations and demonstrations in the O.P. departments on the various phases of rectal disease. At the Queen's Hospital, Hackney-road, there will be a special course lasting a fortnight from April 20th to May 2nd. This will embrace work in all departments pertaining to children's disease, and the instruction will be continued throughout the day, mornings and afternoons. Early application is requested for these courses, and copies of the syllabus may be obtained on application to the secretary to the Fellowship, 1, Wimpole-street, London, W.

In May the following courses will be given: Dermatology at the Hospital for Diseases of the Skin, Blackfriars; diseases of infants at the Infants Hospital; diseases of the throat, nose and ear at the Central London Throat, Nose and Ear Hospital, and psychological medicine at the Maudsley Hospital.

MANCHESTER AND DISTRICT RADIUM INSTITUTE.—At the annual meeting at the Institute on April 2nd the attendance of supporters was the largest on record, and the report presented by the radiologist, Dr. Arthur Burrows, showed that of 843 patients registered, 776 received treatment, the remainder being found unsuitable. The total number of cancerous patients treated was 577. A very considerable improvement of immediate symptomatic cures was noted. At the end of the year 183 patients were described as "well," and 288 as "improved." Ninety-three cases of malignant disease, exclusive of rodent ulcer, were rendered free from symptoms and signs of disease. The number of rodent ulcers treated was 101, and of these 53 were "well" at the end of the year. The total number of out-patient attendances was 6234, and the number of in-patients 966. Of the 12 beds for in-patients, eight are used for non-paying patients. Last year the expenditure exceeded the income by £855. Sir William Milligan, honorary secretary and treasurer, said they were probably a long way from the actual cure, but they were definitely arresting the disease for periods of three, five, and seven years among people pronounced by the most competent surgical authorities as inoperable and incurable.

NORWICH CONTRIBUTORY SCHEME.—The income of the Norwich Hospitals and Medical Institutions Sunday and Saturday Fund last year amounted to £27,065; £24,326 of this was raised by the contributory scheme. Eleven institutions benefit by this money.

ST. THOMAS'S HOSPITAL, LONDON.—The Court of Chancery has sanctioned a scheme, which will cost £58,000, for the extension of St. Thomas's Hospital. A building is to be erected in Lambeth Palace-road, near the hospital, for the accommodation of the students and staff, which will include a club in connexion with the medical school.

THE Medical Missions Department of the Society for the Propagation of the Gospel is holding the annual meeting this year in the Great Hall of the Church House, Westminster, on April 22nd, at 8 P.M. The chair will be taken by the Bishop of Singapore, and Dr. F. S. Drewe, who is home on furlough from Holy Cross Hospital, East Pondoland, will show some new slides illustrating his work there.

NEWCASTLE ROYAL INFIRMARY.—At the annual meeting last week serious overcrowding was reported. Although during the past year the number of emergency beds put up had reached 1600, more than 1000 patients are awaiting admission. An average of 46 accident cases are treated daily, and increased sickness among the nursing staff is attributed to the overcrowding of the wards. The workmen's contributions reached £46,000.

LEEDS INFIRMARY.—The board report that last year's income showed a deficiency of £27,000, and that while the work grows rapidly they have neither buildings nor money to meet it. At the end of the year 1347 patients were awaiting admission. The 18,000 accident and emergency cases were swollen by the increase in motor accidents, and the nursing staff has had to be increased by two-thirds.

STRASBURG: POST-GRADUATE COURSE ON TUBERCULOSIS.—In October a post-graduate course on pulmonary tuberculosis will be held at the Faculty of Medicine of Strasburg, under the auspices of the Anti-Tuberculosis Association of Alsace and Lorraine. A comprehensive programme of lectures and practical demonstrations dealing with many aspects of tuberculosis has been organised by Dr. Vaucher, of the University of Strasburg, from whom further particulars may be obtained at 22, rue de l'Université, Strasburg.

POST-GRADUATE STUDY IN VIENNA.—The seventeenth medical post-graduate course, organised by the Medical Faculty of Vienna, will be held in Vienna from June 30th to July 4th inclusive, when a series of lectures and demonstrations will be given on the subject of modern therapy. Special courses in the various branches of medicine are also held monthly, and foreigners are especially welcomed. Full information and a detailed programme of the courses may be obtained on application to the Dean of the Medical Faculty, The University, 1, Ring des 12 November, Vienna.

NATIONAL ASSOCIATION FOR THE PREVENTION OF INFANT MORTALITY AND FOR THE WELFARE OF INFANCY.—From April 23rd to June 25th Dr. Cicely Peake will deliver at Carnegie House, 117, Piccadilly, W. 1, on Thursdays, from 7.30 to 8.30 P.M., a course of elementary lectures on infant care, especially intended for creche nurses and probationers. For the whole course of ten lectures the fee will be 10*s.*, for any single lecture 1*s.* 3*d.* An examination for the creche nurses' elementary certificate will be held on June 27th at 2.30 P.M. Tickets can be obtained either from Miss Maddock, secretary of the National Society of Day Nurseries, 117, Piccadilly, W. 1, or Miss Durst, secretary, National Association for the Prevention of Infant Mortality, at the same address.

DUBLIN ROYAL VICTORIA EYE AND EAR HOSPITAL. This institution has just been awarded a legacy which will enable it to build a new wing and so complete the original plans for the hospital. The money constitutes the residue of the estate of a Mrs. Lewis, who directed that it should be used to build a hospital in Dublin. The sum (amounting to about £20,000) proved to be insufficient for this purpose and the executors therefore asked the direction of the courts as to the disposal of the money. A large number of hospitals presented their claims before Mr. Justice Meredith and it was expected that he would distribute the money between several charities, as had been done in previous cases by the Irish courts. He decided, however, to keep the sum intact. Whatever hopes in regard to other institutions have been disappointed, it will be agreed that Mr. Justice Meredith has made a proper and fair disposal of the fund.

HOUSING IN DUBLIN.—A conference of those interested in the improvement of housing in Dublin was held last week at the Mansion House, Dublin. Among the speakers was Dr. Dwyer, one of the Commissioners charged with the administration of the city, who stated that since the Commissioners had been appointed they had closed 52 insanitary houses, using a barracks handed over to them by the Government to house those dislodged. They could not close insanitary houses more rapidly because they had no place to put the occupants. They intended to ask the ratepayers to face a large increase in the estimates for building. The conference established a Central Housing Council for the purpose of stimulating and educating public opinion, and of carrying out a publicity campaign culminating in a Housing Week. The ultimate objects of the Council are to improve tenement houses, to assist voluntary housing schemes, and to press for a corporation housing loan.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Friday, April 17th.

ELECTRO-THERAPEUTICS: Extra Meeting, 8.30 P.M.

Papers:

Sir Henry Gauvain: The Organisation and Work of a Light Department in a Surgical Tuberculosis Hospital.

Dr. G. Murray Levick: The Selection of Apparatus for the Production of Artificial Sunlight.

Prof. Russ and Dr. Peacock: Ultra-violet Radiation.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

TUESDAY, April 14th.—11 A.M., Dr. McDougal: Electrical Dept. 12 noon, Dr. Burrell: Chest Cases. 2 P.M., Mr. Sinclair: Surgical Out-patients.

WEDNESDAY.—2 P.M., Dr. Dowling: Skin Dept. 2 P.M., Dr. Burnford: Medical Wards. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—11 A.M., Sir Henry Simson: Gynæcological Wards. 12 noon, Mr. Sinclair: Abdominal Surgery (Lec.). 2 P.M., Mr. Simmonds: Surgical Out-patients.

FRIDAY.—10 A.M., Mr. Dudley Buxton: Dental Dept. 10.30 A.M., Dr. Pritchard: Medical Wards. 2 P.M.. Mr. Vlasto: Throat, Nose, and Ear Dept.

SATURDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, April 17th.—4 P.M., Dr. Dan McKenzie: Diseases of the Labyrinth.

Appointments.

MARTIN, BASIL W., M.B., B.Ch. Aberd., has been appointed Regional Medical Officer to the Ministry of Health.

RAE, H. J., M.B., B.Ch. Aberd., D.P.H., County Medical Officer of Health, Aberdeenshire.

Royal Victoria Infirmary, Newcastle-upon-Tyne: DAVIDSON, S. WHATELY, M.D., B.S. Durh., M.R.C.P. Lond., Honorary Assistant Physician to the Electrical and Massage Department; ARMSTRONG, C. N., M.B., B.S. Durh., B.Hy., D.P.H., Honorary Medical Registrar; COLE, A. H., M.B., B.S. Durh., ALLAN, S. B., M.B., B.S. Durh., LISHMAN, F., M.B., B.S. Durh., STOKOE, J., M.B., B.S. Durh., House Physicians; YEOMAN, J. C., M.B., B.S. Durh., MILBURN, K. V., M.B., B.S. Durh., BELL, D., M.B., B.S. Durh., JONES, M. H., M.B., B.S. Durh., OGILVIE, A. G., M.B., B.S. Durh., COLTMAN, J. F., M.B., B.S. Durh., House Surgeons; NAISMITH, J. J. D., M.B., B.S. Durh., HOLME, R. E., M.B., B.S. Durh., MEEK, T. H., M.B., B.S. Durh., LASCELLES, W. F., M.B., B.S. Durh., SCHOFIELD, C. B., M.B., B.S. Durh., and HARTLEY, J. BLAIR, M.B., B.S. Durh., House Surgeons to Special Departments.

Vacancies.

For further information refer to the advertisement columns.

Bath, Winlsey Sanatorium.—Asst. R.M.O. £250.

Belfast, Ulster Hospital for Children and Women, Templemore Avenue.—Hon. Asst. Surg.

Birmingham, Queen's Hospital.—Res. Anæsthetist at rate of £70 to £100. Also Clin Asst. Hon. £50.

Birmingham Union, Selly Oak Hospital.—Jun. Res. Asst. M.O. £300.

Blackburn and East Lancashire Royal Infirmary.—Third H.S. £150.

Brighton, New Sussex Hospital, Windlesham-road.—Hon. Asst. Anæsthetist.

Bristol, Southmead Hospital.—Res. Med. Supt. £650.

British Hospital for Mental Disorders, &c., 72, Camden-road, N.W.—Hon. Phys.

Cairo School of Medicine.—Asst. Prof. of Chemistry. L.E. 720.

Cardiff, Prince of Wales's Hospital for Cripples and Limbless.—Res. H.S.

Chester, City and County of.—Asst. M.O.H. and Asst. Sch. M.O. £600.

Chorley, Lancs, Chorley Hospital.—H.S. at rate of £150.

Croydon County Borough.—Deputy M.O.H. and Deputy Sch. M.O. £780.

Derby, County Mental Hospital, Mickleover.—Jun. Asst. M.O. £350.

Dorset County Hospital, Dorchester.—Hon. Dental S.

Eastcote, Middlesex, St. Vincent's Orthopædic Hospital.—Res. M.O. at rate of £150.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Res. M.O. £200. Also H.P. at rate of £125. Also Morning Cas. O. at rate of £120.

Evelina Hospital for Children, Southwark, S.E.—H.S. at rate of £120.

French Hospital and Dispensary, 172, Shaftesbury-avenue, W.C.—Radiographer.

Huddersfield, Storthes Hall Mental Hospital, Kirkburton.—Asst. M.O. £400.

London Lock Hospital, 91, Dean-street, W.—H.S. at rate of £200.

London Temperance Hospital, Hampstead-road, N.W.—Surg. Reg. 40 guineas.

Manchester Royal Infirmary.—Asst. Res. Surg. O. at rate of £150. Also H.S. to Aural, &c., Dept., at rate of £50.

Metropolitan Hospital, Kingsland-road, E.—H.P., H.S., Jun. H.P., Jun. H.S., and two Cas. O.'s. Each at rate of £100. Also Surg. for Dis. of Nose, Throat, and Ear.

Newcastle-on-Tyne, Ministry of Pensions Hospital.—Jun. M.O. £350.

Newcastle-on-Tyne, Royal Victoria Infirmary.—Med. Reg. £50.

Nottingham, Bagthorpe Institution and Infirmary.—Res. Asst. M.O. at rate of £300.

Oldham Union, Poor-law Institution, Rochdale-road.—Res. Asst. M.O. £300.

Prince of Wales's General Hospital, Tottenham, N.—Hon. Surg. Reg. and Hon. Med. Reg. Each £200. Also Hon. Asst. S. to Ear, Nose, and Throat Dept.

Putney Hospital, Lower Common, Putney, S.W.—Res. M.O. £150.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Clin. Asst.

Sheffield City Hospital.—Two Asst. M.O.'s £300 and £250 respectively.

Sheffield Royal Infirmary.—Surg. Reg. £200. H.S. £80. Also Dental S.

Sutton, Surrey, Downs Hospital for Children.—Asst. M.O. £550.

The Secretary of State for the Home Department gives notice that he proposes to appoint two more Physicians as additional Medical Referees under the Workmen's Compensation Act, 1906, for the Sheriffdom of Lanarkshire. Applications for the posts should be addressed to the Private Secretary, Scottish Office, and should reach him not later than April 29th, 1925.

Births, Marriages, and Deaths.

BIRTHS.

BARKLEY.—On April 1st, at Woodcroft, Weybridge, the wife of Dr. T. Yuille Barkley, O.B.E., of a son.

HINE.—On March 30th, at Rossmore, Roseberry-avenue, Harpenden, the wife of Montague Hine, M.D., F.R.C.S., of a son.

ILOTT.—On March 28th, at Garden-road, Bromley, Kent, the wife of Cyril H. Ilott, M.B., of a daughter.

ROSSDALE.—On March 31st, at Upper Berkeley-street, the wife of Dr. George Rossdale, of a son.

SNEYD.—On April 3rd, at Harley-street, the wife of George C. Sneyd, F.R.C.S.Irel., of a son.

DEATHS.

CRAWFORD.—On April 1st, at Addison-road, Kensington, W., William Thomas Crawford, M.D., of Worksop, Notts.

HAYWARD.—On April 3rd, suddenly, at Meigle, Scotland, Charles W. Hayward, M.D., D.P.H., Barrister-at-Law, of Prince Edward-mansions, London, W., and late of Liverpool.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE HISTORY OF MINING HYGIENE,

WITH SPECIAL REFERENCE TO THE MINES OF THE WITWATERSRAND.[*]

BY CHARLES PORTER, M.D., B.CH. IREL.,
M.R.C.S. ENG., D.P.H. CAMB.,

MEDICAL OFFICER OF HEALTH, JOHANNESBURG; LECTURER IN PUBLIC HEALTH TO THE WITWATERSRAND UNIVERSITY, AND MEMBER OF THE PUBLIC HEALTH COUNCIL OF THE UNION OF SOUTH AFRICA.

As head of the Department of Public Health, it falls to my lot to inaugurate the first course in mining hygiene, not only of our young and progressive University but, so far as I can ascertain, the first course of this nature which has been offered by *any* educational body. From ancient writings and from the discovery of various, almost prehistoric, mine workings we know that the recovery from the earth of its mineral treasures has engaged the activities of man from very early times.

As regards *mine ventilation*, Pliny (A.D. 60) wrote :—

> " In deep shafts, the occurrence of *Sulphurata* or *Aluminosa* vapour is fatal to the diggers. The presence of this peril is shown if a lighted lamp let down into the shaft is extinguished. Apart from these evils, the air itself becomes noxious with depth, which can be remedied by constantly *skaking linen cloths*, thus setting the air in motion."

Agricola, the sixteenth century author of a quaint and delightful storehouse of ancient mining information entitled " De Re Metallica," further tells us that—

> " Air is driven into the extremities of deep shafts and long tunnels by powerful blowing machines . . . . which the Greeks call *Pneumatika* and the Latins *Spiritales*—though they do not give off any sound—which enable the miners to breathe easily and carry on their work."

Precautions against *falling rock* were also enforced, and Diphilus, a rich mine-owner at Athens, was denounced by Demosthenes and condemned to death for avariciously removing the supporting pillars from his silver mine, which by law he was strictly forbidden to do.

As regards the workers, we know that they were usually slaves, very frequently prisoners-of-war, whose fate, with forced labour, insufficiency of food, and horrible surroundings was indeed dreadful. For centuries, in later times, and in various countries from Sicily to Iceland and Poland to Siberia, the life of the mine-worker was too often synonymous with a living death, and we know that even in England till (as time goes) a comparatively recent date his lot was indeed unenviable and apparently brutalising.

During an official residence of some 12 years between 1891–1902 in the North of England, although one heard of miners' nystagmus, of mine-gas explosions, of heavy mortality among tin-miners, and of miners' dwellings (especially perhaps in the county of Durham) overcrowded and wretched, yet one never heard any mention whatever of the necessity of *underground* mining hygiene, except in connexion with an outbreak of enteric fever in the late 'nineties, ascribed to the drinking in a northern mining village of water pumped from a mine contaminated by infected underground workers. A serious outbreak of hookworm amongst the tin-miners in Dolcoath, Cornwall, in 1901 seems to have marked the dawn of recognition in England of the necessity of freeing mines from fæcal pollution, as had already been advocated in Belgium and Germany. Following investigation by Dr. J. S. Haldane, F.R.S., a service of underground pail-closets was established and strict orders issued for preventing excremental fouling. But for many years afterwards no serious general attempt was made to enforce this important aspect of mining hygiene in England, though it is understood that, comparatively recently, mine-owners have been invested under the Coal Miners Act of 1911 and the Mining Industries Act of 1920 (Ch. 50, 10 and 11 Geo. V.) with this responsibility, as well as others, such as the provision of baths and of means for drying clothes. One is unaware, however, that any special responsibilities are imposed in regard to the purity of underground drinking water.

Historical Survey of Mine Sanitation on the Rand.

In Johannesburg, previous to 1903, the " mines " were outside the municipality; mines sanitation was practically non-existent, except in regard to matters in connexion with ventilation, blasting, and change houses. No provision was made for disposal of excrement underground, and night-soil removal from the surface works was carried out, more or less perfunctorily, by private contract. In October, 1903, the extension of the municipal area brought in the mines and it was arranged between the mining authorities and the council's representatives that all matters of surface sanitation, such as native quarters, housing, water-supply, and refuse removal services, be controlled by the municipality, through a specially selected mines sanitation inspector directly responsible to the medical officer of health. As regards underground drinking-water supplies, excrement disposal, &c., this inspector was placed under the directions of the Government mining engineer, but did not officially concern himself with the very technical problem of ventilation, and this arrangement has been found during the succeeding 20 years to be particularly satisfactory to all concerned, and especially appreciated by mine managers. The work of the late Mr. Alexander Cowie, C.E., the first mines sanitation inspector on the Witwatersrand, was uniformly excellent, tactful, and most effective, and the following extracts from his first annual report are very interesting :—

> " It is gratifying to be able to state, as regards surface arrangements, that recommendations and notices under the Public Health By-laws are almost invariably found on reinspection to be complied with . . . . the almost general provision of comfortable housing accommodation, of all necessary sanitary conveniences, and of systematic and approved scavenging arrangements, testifies to the fact that the requirements of good sanitation are far from being looked upon as a secondary consideration."

As regards *underground* sanitation, Mr. Cowie wrote :—

> " Strict attention is paid to securing on each working level, at suitable sites, a sufficient number of sanitary conveniences, properly ventilated, lighted, and disinfected. The maintenance of careful general scavenging throughout the workings is also called for. A detailed report is furnished after each inspection to the Inspector of Mines for the Johannesburg district, and a copy of each such report is forwarded by him, through the Mines Department, to the Mine Managers and to the M.O.H. Johannesburg, for information. Night-soil from the mines is brought to the surface in buckets with clamped water-tight covers, and their subsequent cleansing and disinfection are attended to by the Municipal Scavenging Department."

The opening years of the present century were, however, both in England and South Africa, marked by considerable activity in other and wider directions affecting the health of the mining workers, and notably in regard to the scourge of miners' phthisis. That certain dusts are peculiarly productive of phthisis has long been recognised, and as far back as 1864 the undue mortality from diseases of the lungs among English metalliferous miners had been reported by the late Dr. Farr to a Royal Commission appointed in that year. The recommendations of this Commission were in the main carried out, but this undue mortality still persisted and seemed indeed to be associated with metalliferous mining in most parts of the world, being specially notable in Cornwall, where many of the sufferers were said to be returned Transvaal miners.

Dr. Haldane, with whom were associated Messrs. Martin and Thomas, were, therefore, commissioned in 1903 to inquire into and report on the health of the miners employed in the mines in Cornwall, with special reference to the injurious effects alleged to be produced by the state of ventilation in the mines, the dust arising from the use of rock-drills, and the introduction of impurities into the working places through the use of compressed air. They reported in 1904, recommending the prohibition of percussion rock-drills in hard stone, without satisfactory precautions for preventing the inhalation of dust; the enactment of special rules for minimising the inhalation of dust, and securing a suitable and cleanly excrement removal service.

At this period, however, the mortality from silicosis was notoriously greater on the Witwatersrand than anywhere else, and in December, 1902, Lord Milner appointed the first Transvaal Miners Phthisis Commission to inquire into the extent and cause of this condition and the measures necessary for combating it. In May, 1903, this Commission recommended water-sprays and jets for minimising the dust produced by rock-drill and blasting operations, the adequate ventilation of the working places, the provision of an efficient sanitary system, and of suitably warmed and convenient change houses, and the non-use of low-flash-point lubricants in the air cylinders of compressors.

In 1904 Lord Milner nominated a further Commission to investigate and report on the accommodation and air space required in the compounds for coloured employees of the mines of the Witwatersrand district. The main result of its deliberations was the evolution of the Rand mines type of hut in which the importance of adequate air change, in contradistinction to cubic space allowance per head, was accorded fuller recognition than had previously been the case, such cubic space allowance being fixed at 200 cubic feet per head, in view of the special facilities provided for free ventilation and air change. With some modifications suggested by experience, this type of hut still enjoys official sanction.

---

[*] An address delivered at the Witwatersrand University.

In 1907 Lord Selborne gazetted the Mining Regulations Commission to undertake a general revision of these regulations with special reference (inter alia) to ventilation, underground sanitation, and change houses. This Commission's inquiry covered nearly the whole range of mining hygiene, and its members had the satisfaction of seeing effect given to most of their recommendations within a quite unusually short period.

Miners' Phthisis.

Prominent amongst those who assisted these various commissions with their considered experience and the results of their special study of this subject was the late Dr. Donald Macaulay, in association with Dr. Louis Irvine, now a very senior member of the expert medical staff which has made the work of the Miners' Phthisis Medical Bureau so widely known and appreciated. It is both a duty and a privilege, especially in a community where such services are so soon and callously forgotten, to recall the fine pioneer work of these two keen investigators in this and other important aspects of mining hygiene. Early in the career of the first Government of our newly-formed Union, it passed the Miners Phthisis Allowances Act, No. 34, of 1911, and at once appointed yet another "Miners' Phthisis Commission" to report on the extent to which the disease was prevalent, the degrees to, and the stages at which incapacitation occurred, and the necessary medical considerations to be borne in mind in connexion with the statutory provision of compensation.

This Commission was followed in 1912 by the creation of a standing advisory body, the Miners' Phthisis Prevention Committee—

> "To inquire into by experimental or other investigations and to report from time to time upon the improvement of the methods for the prevention of Miners' Phthisis in the Witwatersrand Gold Mines, and to advise upon the introduction of a systematic and uniform policy and the amendment of the Mining Regulations which may be necessary for combating the disease."

This Commission submitted its final report in 1916.

Lastly, on August 1st, 1916, the Miners' Phthisis Medical Bureau was instituted, its chairman being Dr. Watkins Pitchford. Its main object and functions are :—

1. To examine all persons presenting themselves for employment on the scheduled mines and to determine those who are suitable for underground employment.
2. To examine all working miners at intervals of six months with the object of detecting the presence either of silicosis or of tuberculosis in such miners.
3. To examine all applicants for compensation on the ground of the presence of silicosis or tuberculosis and to determine in what stage, if any, of the former disease, such applicants may be.
4. To supervise in the cases of native mine employees similar examinations which are actually conducted by the medical officers of the mines. No compensation, however, is granted to any native until he has been examined by the Medical Bureau.

The following brief account of the results of the working of the Bureau and of the present position was supplied by Dr. Pitchford at my suggestion in 1922 for the information of the mining industry in Australia. It has kindly been brought up to date by Dr. Irvine, and is of a very interesting and striking nature.

Since the passing of the Miners Phthisis Act of 1916 and up to July, 1924, two cases only of silicosis have originated in men (whether previously miners or not) who have been passed as fit for underground work at the initial examination of the Bureau. During this period 12,381 European men have received certificates of fitness to follow mining work, and 6132 of these are known to have obtained underground employment. As the total number of European miners is about 14,000, and the average number actually engaged in underground work in scheduled mines during the year is only 10,000 or 11,000, it is evident that a substantial proportion of the latter are men who hold the certificate of initial fitness.

Silicosis.

All the cases of silicosis, whether complicated or not by tuberculosis, with the exception of the two mentioned which have originated amongst our miners since 1916, have, then, been in "old miners"—men who, being in employment prior to 1916, were not required to pass the initial medical examination. It is not contended that this relative freedom from silicosis of those who have been recruited since 1916 is entirely due to the exclusion of physically unsuitable men by the initial examination ; for the continuous improvement in underground conditions of work, which has been going on since about the year 1911, must now be bearing fruit. Managements and men are at present unanimous in their efforts to carry out the dust-prevention regulations.

The prevention of dust, however, would not, by itself, suffice to prevent the spread of the disease, especially tuberculosis, amongst the miners. Our law requires every miner to be medically examined at least once in six months, in order to detect those who have developed tuberculosis. This enables the Medical Bureau to secure the prompt removal of every person who is tuberculous and thus to protect the other miners from infection. A man who has developed silicosis is also notified of the fact, so that, if he desires, he may make application for compensation. The great majority do so. But if a man develops tuberculosis, whether or not he also has silicosis, he is obliged to give up his occupation at once.

The number of working miners who have been found to be the subjects of silicosis complicated by tuberculosis for each year since 1917 has been 116, 120, 24, 17, 24, 19, and 20. This reduction is gratifying. Pulmonary tuberculosis, without silicosis, is now considerably less common among our miners than it is among the male population of the industrial towns of England and Wales. No case of silicosis in the secondary stage has originated amongst our employed miners since the year 1919.

The consolidating and amending Miners Phthisis Compensation Act of 1919 introduced a new stage of silicosis which has to be legally recognised—viz., that stage in which the physical signs of the disease first appear in their earliest detectable form. This stage is termed the "ante-primary" stage, because it refers to a condition antecedent to that previously known to all the miners as the "primary" stage. Its recognition obviously requires not only that the miner should be examined by an expert, but also that the expert shall be able to refer to carefully kept records of previous examinations. In the first year in which the existence of this new stage was legally allowed for, 562 cases were certified ; in the second year 219 cases, in the third year 254 cases, in the fourth year 255 cases, and in the fifth year 318 cases, all of them, with the exception of two in the fourth year, being, as already stated, in "old miners."

It is agreed by all impartial observers that the work of the Medical Bureau is indispensable to continued progress. The value of its initial examinations has now become obvious to all, and the service which it renders the individual worker by keeping him periodically informed as to his health with respect to pulmonary disease is greatly appreciated by the miners themselves. It is necessary to point out, however, that the work of the Medical Bureau would not have been so successful were it not for the following conditions : The members of the Bureau devote their whole time to the work and are not allowed to engage in private practice ; the Bureau is appointed and controlled solely by the Government—neither the employers nor the workers have any power of interference with its duties ; and the examinations of the Bureau are always supported by standardised X ray negatives of high technical quality.

Mortality from Pneumonia.

Apart, however, from miners' phthisis, the very great mortality from pneumonia amongst native, and especially *tropical* native, mine-workers gave rise to much misgiving, and in 1911–12 the problem was investigated on the Witwatersrand by Sir Almroth Wright, who reported in 1913 recommending anti-pneumococcal inoculation as the most promising preventive measure. His researches were continued by our friend, Sir Spencer Lister, who, after careful study of the various forms of pneumococcus found in association with the disease, produced a vaccine which, at a conservative estimate, has reduced this pneumonia mortality from 40–50 per cent., an achievement which has made him deservedly famous, and of which all his confrères are very proud.

Lastly, in December, 1913, at the suggestion of Mr. Samuel Evans, the late General Gorgas, known all over the world as the man who made work in the Panama Canal area possible from the health point of view, was invited by the Chamber of Mines to visit and report on the health conditions of our mines, especially in relation to the prevalence of pneumonia amongst natives. His chief recommendations were the provision of a larger amount of floor space for each occupant of the compounds ; also, where possible, their dispersion from large barracks into single huts and small rooms ; and, secondly, the reorganisation and centralisation of the native hospital system.

The Present Position.

As regards the practice of mining hygiene in Australia, one ventures to think, from some personal observation and considerable inquiry, that the Witwatersrand has little, if anything, to learn from that Dominion. Judging, too, from the very brief references in the long series of fine annual reports of the Surgeon-General of the Public Health Services, the same remark applies to the practice of mining hygiene in the United States of America.

Even from the foregoing somewhat hastily compiled résumé of the efforts by Government and by the mining industry during the last 20 years, not only to minimise but, if possible, to "cut out" miners' phthisis and pneumonia as the most deadly factors in mining mortality, and generally to create a healthy environment amongst its mine-workers, one submits that the Witwatersrand has to a large extent led the way in showing the world how such problems may be tackled with a large and promising measure of success. Those who have had even any small share in this work are rightly proud of it; and one recalls with pleasure and gratification the words in which the Right Hon. J. H. Thomas, M.P., Colonial Secretary of the late English Labour Government, after a morning spent during his recent visit in examining the surface works and the conditions of white housing on one of our great mines, publicly stated that he had been immensely impressed by what he had seen, and by the fact that the conditions under which the workers lived were far better than anything that could, he feared, be hoped for in the Old Country. With a personal knowledge of these conditions in both countries, one entirely accepts this statement.

Coming to the course of lectures now inaugurated, one recalls a remark by that charming gentleman, the late General Gorgas, that the Witwatersrand's wealth of clinical material marked it out as the seat par excellence of a medical school: and I think that a similar statement applies with equal force to its facilities for the study of mining hygiene. The desire of this University and the industry is to assist in every way in utilising these advantages, and our acknowledgments and thanks are specially due to the Rand Mines Group, which has now made it possible to take the first step in training mine officials of all classes to appreciate the real necessity and benefit of the high standard of hygiene that has been laboriously reached, and the duty of all of them to assist in maintaining and improving it.

The unique course now instituted covers housing, clothing, and diet of natives, sewage and refuse disposal in its widest meaning, mine ventilation, the administration of mine hospitals, the physical examination of native recruits, the work of the Miners Phthisis Medical Bureau, the management of epidemic outbreaks, and the prevention of accidents. I have little doubt that this very comprehensive and useful course will prove not only of very live interest, but of material practical benefit to officials as well as to the mine-workers—both white and coloured—for whose welfare they work.

PUBLIC HEALTH AT HONG-KONG.

THE civil population of Hong-Kong in 1923 was estimated at 597,300, of which total 15,500 were "British and foreign civilians," the remainder being Chinese. The general birth-rate for civilians is said to be 7·39, and that of the Chinese 6·97 per 1000; but "from the nature of the case, it is practically impossible to arrive at a correct estimate of the Chinese birth-rate." The general civilian death-rate in 1923 was 25·98 per 1000, for Chinese 26·27, and for non-Chinese 14·83. The total deaths at 1 year of age or less numbered 4556 Chinese and 29 non-Chinese; the infantile mortality ratio for the latter was 81·23 per 1000 births. At the three principal hospitals in the colony, the Government civil, the Tung Wah, and the Kwong Wah, the total patients treated increased from 17,937 in 1922 to 22,292 in 1923. The chief diseases were beri-beri (2091 cases), malaria (1640), pulmonary tuberculosis (1029), and syphilis (830). Dr. J. B. Addison, principal civil medical officer, states in his report[1] with regard to beri-beri that he "was informed that there was an increase in the price of provisions, and this must have led the poorer classes to live more than ever on an extensive [? exclusive] rice diet, the only rice commonly used being the white polished variety." There was a large increase in malarial cases treated at the three hospitals mentioned, from 921 cases in 1922 to 1640 in 1923; the incidence was specially noted amongst Chinese policemen recruited from Wei-hai-wei (on the coast of Shantung province, N. China). At the Kwong Wah Hospital 6359 in-patients were treated, of whom 39 per cent. received Chinese treatment and 61 per cent. Western treatment, as compared with 30·9 and 69·1 per cent. in the previous year respectively; 68,179 out-patients were treated, 64·2 by Chinese methods and 35·8 per cent. according to Western practice. In 1922 the corresponding percentages had been 40·2 and 59·8 per cent.; the preference for Chinese treatment appears to be decided, and the decrease in Western treatment seems regrettable, and to need attention. At the Tung Wah Hospital, Victoria, 10,478 in-patients were treated, a considerable increase on those treated in 1922 (8336); in this hospital 4823 and 5655 received native and Western treatment respectively, as compared with 3714 and 4622 in 1922. The out-patient visits numbered 170,858, as compared with 168,951 in 1922. The cases taking native treatment decreased from 136,280 in 1922 to 124,120 in 1923; while those taking Western treatment increased from 29,722 to 42,302; in addition the visits at the Eye Clinic (under Western treatment) increased from 2949 to 4436. The difference in the amount of acceptance of Western treatment in the different institutions is noteworthy, and invites inquiry as to the reason for this difference.

Hong-Kong ranks fourth in the world's seaports in regard to "tonnage entered," and second for "tonnage cleared" (14,922,232), being only surpassed in this respect by New York. The inward-bound ocean steamers numbered 6321, all of which were visited by the health officers; 249 arrived in quarantine, and both passengers and crews (numbering 32,189 persons) were examined before *pratique* was granted; only eight of these vessels were detained in quarantine, small-pox (8 cases) being the reason; the vessels were fumigated and disinfected, and all persons on board vaccinated. The total persons examined amounted to 210,810, averaging 575 examinations for each day in the year.

HEALTH CONDITIONS IN SIERRA LEONE.

Mr. G. C. Du Boulay, Acting Colonial Secretary, has been responsible for the preparation of the annual report for 1923. It states that the number of European residents during the year in the colony and Protectorate was: officials, 188; non-officials (including white Americans), 420; military, 486. The population of Freetown was, according to the census of 1921, 44,142, and the birth-rate per 1000 in 1923 was 19·3, and the death-rate per 1000 30. In the colony other than Freetown the population was 41,021, the birth-rate 18·7 per 1000, and the death-rate 21·5 per 1000. Owing to the non-registration of many births the "available" birth-rate is undoubtedly much below the actual birth-rate, and for this reason the infantile mortality-rate (437 per 1000 in Freetown and 261 in the colony other than Freetown) appears a good deal higher than it really is. It is nevertheless excessively high, and infant welfare work is being undertaken on an increasing scale with a view to reducing it. According to the census figures the males exceeded the females by 28·5 per cent. and 24·3 per cent. in Freetown and the rest of the colony respectively. This is an additional factor in producing the low birth-rate. Two cases of small-pox were reported in Freetown and there were 17 cases in the Protectorate. Chicken-pox was fairly frequent both in the colony and in the Protectorate. 21,517 persons were vaccinated during the year, of which 10,294 were successful, 4266 unsuccessful, and 6957 not inspected.

A census of the colony and Protectorate was taken in November, 1921. The report, published in 1922, shows that the population has increased from 1,403,132 in 1911 to 1,541,311 in 1921. The population of the colony proper shows a very considerable increase—viz., from 75,572 to 85,163. This increase is wholly due to a striking augmentation of the population of Freetown—viz., from 34,090 to 44,142. The estimated native population of the Protectorate has increased from 1,323,151 in 1911 to 1,450,903 in 1921.

The Colonial Hospital was completely destroyed by fire early in 1920 and all records were burnt. A portion of the new hospital was completed in 1922, consisting of three blocks of two wards each, operating theatre, kitchen, laundry, fumigatory block, and staff latrine and bath block. In addition to the foregoing, the new hospital was planned to comprise three more blocks for Africans, one for Europeans, quarters for the resident surgeon and nursing sisters, offices, and stores. No work was undertaken in these additions in 1923, but a resumption is contemplated at an early date. Patients admitted to the Colonial Hospital during the year numbered 1577, and there were 121 deaths; 71 operations were performed. 200 patients were admitted to the maternity ward, the largest number recorded. 11,355 out-patients were treated in the hospital, the total attendances being 48,320. At the lunatic asylum, Kissy, there were 101 inmates on Dec. 31st, 1922; 56 were admitted during 1923, and 23 died. The patients who are mentally and physically fit are employed on light work. There were 281 admissions to the Kissy infirmaries during the year; a total of 349 cases were treated, and there were 47 deaths. To the nursing home there were 131 admissions, 50 being Government officials; 2 non-officials died.

The climate of Sierra Leone is tropical with a heavy rainfall and high atmospheric humidity during the greater part of the year. The shade temperature rarely falls below 70° F. On the other hand it rarely rises, even in the dry season, above 95°, and there is always a sufficient daily range of temperature to render the mornings and evenings relatively cool. It is not always damp. Speaking generally, there are four months of very dry weather when little or no rain falls, and four months of varying conditions with a moderate rainfall for a tropical country. There is a single rainy season lasting, roughly, from May to the end of October. This occurs during the period of the south-west monsoon. It is preceded and followed by a period of thunder-storms known as tornadoes, which travel in a direction from east to west. The rainfall in 1923 (125 inches) was almost exactly equal to the average for the past ten years, but a good deal below the average for the past 40 years.

---

[1] Hong-Kong Government Printers. 1924.

There are facilities for playing cricket, football, tennis, and golf in Sierra Leone. As the country is hilly, cycling is laborious and horses do not thrive; but for some distance out from the town the roads are good enough for motor-cars and motor-cycles to be used. Local meat is by no means as good as good English meat, but when properly cooked is quite nutritious. Excellent fresh fish can be bought, and, apart from potatoes and onions, which are imported, fresh vegetables and fresh fruit can be obtained at reasonable prices throughout the year.

ABERDOVEY.

THIS is a popular health resort on the west coast of Wales, six hours' journey by express from Paddington; it has a sheltered and sunny climate, and although there is a considerable rainfall the winter and spring months afford, as a rule, a gentle retreat by comparison with eastern and northern England. With the object of making Aberdovey better known the Town Improvements Committee, of which Dr. F. S. Jackson is the honorary secretary, have issued a new official illustrated guide containing an account of the historical and legendary history of the town "leading back into the darkest ages of antiquity," together with notes on the opportunities offered for golfing, bathing, boating, angling, walking, cycling, and motoring.

A FRENCH SPA.

VITTEL, a well-known French spa, was founded in 1854 by Louis Boulomié, who conceived the idea of erecting a town around the springs of medicated water at that spot. His son, Dr. P. Boulomié, has now written the story of the foundation of this town and its development into a fashionable centre for the benefit of his grand-children (Histoire de Vittel. Paris: Maloine et Fils. Fr.7.50). This little book gives an interesting story in a free and easy style. A short sketch of the founder precedes a description of the gradual growth of Vittel, and abundant photographs illustrate the progress of 70 years. Its extent may be realised from statistics, for in 1860 less than three thousand bottles of water were despatched, while at the present day about 15 million bottles of Vittel water are sent each year to all parts of the world.

OPEN SPACES AND PLAYING FIELDS.

AN appeal has been made by three ex-Prime Ministers and by leading members of all political parties, and many groups of social workers for the formation of a National Playing Fields Association in order to coördinate the activities of local societies in this connexion and to urge the creation of a sub-department of sport in the Ministry of Health. The idea will be welcomed by medical men, who recognise the importance of physical recreation and who support the Metropolitan Public Gardens' Association for the same reason. This Association has for many years done excellent health work by providing or preserving open spaces, and at a recent meeting of the Association at Denison House, Vauxhall Bridge-road, the President, Lord Meath, announced that Sir Henry Cowan, M.P., was about to introduce the Open Spaces Bill for giving additional powers to local authorities to acquire lands for playing fields. The news was also confirmed in regard to Ken Wood that the remainder of the estate had been puchased by Lord Iveagh with a view to its preservation for popular uses.

GARDENING.[1]

MANY of our readers not only love gardens but superintend practically their own gardens or work assiduously in them. And the learned Jonathan Hutchinson's interest in the similarities to be traced between human and botanical development and pathology is shared by many medical practitioners. The work on gardening issued by Messrs. George Newnes, Ltd., whose first instalments reach us this week, will therefore receive support from the medical profession, who will certainly derive from its perusal, judging by the contents of the first two sections, much fundamental information set out in an orderly manner. Especially, with such a work of reference as it promises to be, will it be possible to plan ahead, for a diary is given, corresponding to the date of the section, under which the timely operations for the month are ranged. All who have the control or practical management of a small garden will recall the sort of difficulty which arises when something ought to be sown by a certain date, and when the only suitable spot is already occupied by something which ought not to be sacrificed, but cannot safely be moved at that date. Similar dilemmas will occur to the recollection of everyone who has gardened; they know that such troubles can be avoided by keeping a time-chart, and will welcome the orderly information provided by "The New Book of Gardening."

SMOKE ABATEMENT.

WE have received from the Smoke Abatement League of Great Britain a copy of the report of the successful conference which was held at Manchester in November, 1924. The report of 300 pages is excellently printed, and as many of the problems of smoke abatement were dealt with at the conference by acknowledged experts and from various points of view, the document ought to be in the hands of all who take an interest in the question. The hon. secretary of the League is Mr. C. Elliott, 33, Blackfriars-street, Manchester. The price of the publication is 5*s.*, post free 5*s.* 6*d.*

EYES AND HAIR DYES.

IN the medical report presented to the annual meeting of the Bath Eye Infirmary, the hon. surgeon, Dr. J. Burdon-Cooper, called attention to dangers to the optic nerve caused by the use of hair dyes. "We believe," he said, "this type of case to be on the increase and a warning is needed as very severe trouble may result, and we have known eyes completely lost owing to this practice." He considers that legislation respecting the sale of poisonous dyes is needed.

THE ENERGY EXPENDITURE OF CRYING.

ESTIMATION of the calorie requirements of infants has always been complicated and rendered uncertain by the striking difference which exists between the basal metabolism and the augmented metabolism of an active child. Reference is made (*Jour. A.M.A.*, Feb. 21st, 1925) to a communication of Murlin and others, in which stress is laid on crying as an augmenting factor in metabolism. It is stated that metabolism is doubled during the period in which an infant cries. A sickly child, whose general muscular activity is low, may thus be expending more energy than is commonly supposed. If, as is often the case in healthy infants, crying is accompanied by active movement of the limbs, the total metabolism must obviously be raised to a figure far in excess of the basal rate. These observations have direct bearing on the quantitative aspect of infant feeding; the ease with which extremely large variations in the energy exchange are produced should be borne in mind in all attempts to estimate the food requirements of infants in terms of calories.

THE TEACHING OF MOTHERCRAFT.

As Sir Arthur Newsholme recently pointed out[1] at the annual meeting of the National Baby Week Council, the infantile death-rate had been halved; as a matter of fact the number of deaths under 12 months of age per 1000 babies born has fallen in England and Wales from 154 per 1000 in 1900 to 69 per 1000 in 1923, and he instanced among the chief factors which had produced this wonderful improvement those of publicity and education. For a number of years the Board of Education have had under consideration the teaching of infant care and management to girls in attendance in elementary schools, and some five years ago the Medical Department of the Board prepared a memorandum dealing with the question in some detail. As a result there has been a considerable extension in the teaching of infant care, though much remains still to be done, and a revised Circular (No. 1353)[2] has just been issued by the Board of Education. This important little pamphlet, to quote the words of the preface, should "arouse a keen interest in the subject among many who have not yet realised the opportunities and responsibilities of elementary and other schools in this direction," while serving at the same time as a guide to the many workers who have already recognised the value of the work. As the great majority of the mothers of the future pass through the elementary schools, it is obvious that school teaching of the subject must bear good fruit when motherhood is reached, but further, as quite a large number of girls at school are compelled to play the part of nurses to their younger brothers and sisters, school teaching of mothercraft must have a double benefit. The circular, which is written by Dame Janet Campbell, Chief Woman Medical Adviser to the Board of Education, outlines the course of teaching which it is advisable to pursue, setting forth the method of teaching in elementary, secondary, day continuation and trade schools.

Croonian Lectures

ON THE

RÔLE OF FATS IN VITAL PHENOMENA.

By J. B. LEATHES, F.R.C.P. Lond., F.R.S.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF SHEFFIELD.

LECTURE I.*

Physiological Significance of Fats.

The rôle assigned to fats in physiology is and has been for a long time threefold. In order of precedence determined by seniority these are: that they add beauty to the outline of the human form; that they serve as a protection for delicate organs against injury, and for the body as a whole against cold; and, finally, that they constitute the principal fund of reserve fuel on which the system can draw in times of shortage.

But there have long been indications that the physiology of fats could not be so quickly dismissed. The material that enters into the composition of an organism may be potentially fuel and yet actually something more. If the essential chemical constituent of living matter is protein, the protein of the muscles and of other organs that waste in starvation is clearly the material that supplies the nitrogenous needs of the heart that does not waste.

Is it possible that the fat that is found in the parenchymatous cells of the various organs, though it may at need serve as a source of potential energy, has other more essential functions to perform? Is it possible that any of it is actually, like the proteins themselves, needed for the very maintenance of the form of life, a part of the material that lives? For much the larger part of the fat that is found in the body this possibility is excluded. That is probably why this question is not more frequently put. The days when most of us come fresh to the study of physiology are half of them spent in cutting away fat in the dissecting-room as material that has no interest or significance. In adipose tissue the cells have relapsed into a state of ignoble obesity. They are merely receptacles of riches for others to prey upon. But organs and tissues may be practically free from adipose tissue and yet, when subjected to analysis, they are found to contain fat.

We have in physiology to define fat in our own way. The chemical definition of fat is too narrow. There are compounds of the higher fatty acids which in the narrower chemical sense may not be fats. But the physiological significance of fats resides so largely in the properties of the long chains of carbon atoms of the higher fatty acids that the physiology of fats rests upon the physical and chemical properties of these chains, and cannot be confined to their behaviour only when they are combined with glycerol alone as simple glycerides. Some of the fatty acid chains can only fulfil their physiological destiny by entering into combination, even if it is only temporarily, with other groups besides that of glycerol; and if they do they do not cease for the student of physiology to be fat. That is why in the estimation of fat in animal organs the method now generally adopted is to liberate the fatty acids from all the combinations in which they occur, determine their amount, and give the result in terms of fatty acid.

Differences between Fat in Adipose Tissue and in Organs.

There are three points that the analysis of the fat in animal organs brings out which bear on the physiology of fats, three points of difference between such fat and that which is found in adipose tissue. In the first place the fatty acids, or some of them, are different; in the second the combinations in which they occur are, in part at least, different; and lastly, instead of varying in amount with accidental variations in the state of nutrition, they show a general tendency to remain constant around certain mean values.

Differences in Fatty Acids.

The fatty acids are different. In the adipose tissue of any species the fat has as a rule a certain constant composition, in which saturated and unsaturated acids occur in proportions that are more or less fixed. In different species these are different: lard, suet, tallow, goose-fat differ from one another, but each of them has constant properties, largely, though perhaps not solely, determined by the nature of the food taken by the species of animals in which it is deposited; and in any species the composition may be altered by alterations in the fat contained in the food. These differences in the fat of the adipose tissue are therefore accidental. Adipose tissue fat is, broadly speaking, the fat taken as food. But in the organs the fatty acids are no longer entirely the same; here too, it is true, saturated acids are found, but with them are associated unsaturated acids, other than oleic acid, which are not found in the adipose tissue, and must therefore have been produced in the body. This is shown by the amount of iodine absorbed by the acids which is, except occasionally in the liver, much greater, and shows a constancy that has a different significance from the accidental constancy of the fat of the connective tissue in this respect. Moreover, the acids themselves, or characteristic derivatives of them, can be isolated and identified.

Combinations of Fatty Acids.

The combinations in which the fatty acids occur are different, because a considerable amount of the fatty material is associated with phosphoric acid and groups containing nitrogen, and from the organs lecithine and other compounds of fatty acids which contain phosphorus and nitrogen can be obtained. Direct estimations of the amount of these combinations of fatty acids cannot be made. But the total fatty acids from all combinations having been determined, it is possible to determine the amount of phosphorus present in combinations which are soluble in solvents for fat, and from the proportion between the quantities found, on certain assumptions, inferences can be drawn. Lecithine and cephaline, for instance, yield two molecules of fatty acid for one atom of phosphorus. If the fatty acids have 18 carbon atoms this means that the amount of fatty acid obtainable from these compounds would be about 18 times as great as the amount of phosphorus they contain. If these are the only compounds occurring in an organ that contain phosphorus and dissolve in these solvents it is clear that determinations carried out on these lines tell us the extent to which the fat in an organ takes these forms.

This has been done more systematically in recent years by A. Mayer and Schaeffer,[1] and some of their results are given in Table I., which is from one of their papers.

Table I.—*Value of the Ratio of Total Fatty Acid to Phosphorus Extracted by Fat Solvents in the Organs. (In Lecithine and Cephaline this Ratio is 18.)*

—	Kidney.	Lung.	Pancreas.	Liver.	Serum.
In man (one case)	24·7	—	54·8	36·1	—
Dogs	22·1	22·4	27·0	21·4	23·5
Rabbit	22·0	25·3	—	19·6	13·6
Guinea-pig	24·9	18·8	—	16·0	23·5
Pigeon	26·6	16·5	—	32·6	23·0 Fowl
Horse	—	—	—	20	23·0
Ox	—	—	—	29	23·5
Mouse	—	—	—	28	—
Sheep	—	—	—	—	23·1
Pig	—	—	—	—	23·2

It is clear that interpreting these figures on the implied assumptions we should arrive at the conclusion that considerably the major part, about three-quarters, of the fat in these organs in almost all cases was composed of compounds such as lecithine.

---

* These lectures were prepared for delivery before the Royal College of Physicians of London in 1923. Lectures II., III., and IV. will appear in subsequent issues.

Constancy of the Amount of Fat in the Organs.

Lastly, while the total amount of fat in the body as a whole varies greatly because of the great variations in the amount stored in connective tissues in different states of nutrition, the amount in the organs is subject to variations which are, except in the liver, comparatively small. In the great majority of cases the fatty acids constitute between 2·5 and 4 per cent. of the weight of the organs, or between 10 and 16 per cent. of their dry weight. In the voluntary muscles the amount is sometimes more and the variations are greater. Whether the cause of this variability, so far as it affects the same muscle in the same species, is anything more than the result of the presence of more or less interstitial adipose tissue may be questioned. In the spleen the fatty acids generally amount to less than 10 per cent.

Upon the constancy of the amount of fat in the organs great stress has been laid by André Mayer, Terroine, and others associated with them; and the point which they have brought out which is of greatest significance is that the organs of animals starved to death contain substantially the same proportion of fat as those of animals that have been normally fed. This is a fact that has not generally been expected. When it is said that a starved animal will use up all the fat in its body before it dies, this applies properly only to the fat stored in the adipose tissue. In the organs it is impossible for the fat to be all used up; it is an essential part of the cell substance, and cannot be dispensed with any more than the proteins so long as the cell is alive.

The Cholesterol Content of Fats.

In addition to these three prime differences between the fat of adipose tissue and that found in the cell protoplasm of the organs that do the work of the body, there is a further point of difference the importance of which it is difficult to estimate. While the fat in connective tissues contains only barely detectable amounts of cholesterol, in the organs cholesterol is always present. It appears to be functionally, as well as in part chemically, associated with the fat. Cholesterol esters of fatty acids are found in the blood, in the adrenal gland, and in certain conditions in the kidney. In nervous tissue, which contains more cholesterol than any other, it is found to be chemically free; but it is there anatomically so intimately associated with fatty components that it is difficult to believe that it is not functionally, too, in the closest relationship with them. André Mayer has traced constant quantitative relations between the amount of cholesterol and the amount of fatty acids found in the various organs, which are shown in Table II. He particularly comments on the fact that the differences in this respect found in different organs are the same in the different species examined; in each species the ratio for any organ is remarkably constant, and for all species the ratios for the different organs come out in the same order. The lung gives the highest value, then the kidney and liver follow, and the lowest value falls to muscle. He regards the protoplasm of different types of cells as differing from one another much as do different alloys of the metals, the properties of each type depending upon the proportions in which the ingredients occur in it. In the neuron fatty components and cholesterol constitute nearly 10 per cent., in a liver cell 3 to 4 per cent., in a red blood corpuscle less than 1 per cent. There is more fat and more cholesterol in red muscle than there is in white, and still more in the heart. The relations between cholesterol and fatty acids appears, according to Mayer's observations, to determine the amount of water in proportion to solids held by a type of cell, and also the amount of water that any type of cell will take up when immersed in water. The water taken up varies, he finds, inversely with the amount of fat, and directly with the amount of cholesterol that the cells contain. Thus the lung takes up more water than the kidney, the kidney than the liver, and so on in order down the list shown in Table II. In the muscles which contain varying amounts of reserve fat which is not built up into the protoplasmic fabric, and differ in this respect from other organs, the amount of water taken up varies directly with the cholesterol and inversely with the phosphorus associated with fatty acids; so that they also come into line. In starvation the organs as they waste lose protein and fat in proportion, but appear to retain cholesterol, so that the ratio of cholesterol to fatty acid in the cell rises, and with this change the amount of water taken up by the cells when immersed in pure water is increased correspondingly. (Table III.)

TABLE II.—*Relation Between the Amount of Cholesterol Found in Various Organs and the Fatty Acids they Contain Expressed in Percentage of the Latter. (A. Mayer and Schaeffer.)*

This puts the fats on a different level from that to which they have generally been assigned. Everyone has known that in starvation the brain and nervous system do not lose weight; that means, though it is not usually pointed out, that the organ which contains the largest amount of what may be called organised fat can dispense with none of it if it is to live. And while other organs may lose weight, 30 per cent. or more, the proteins in them appear to be sacrificed as readily as the fat. The original relation between fat and protein is found to have been preserved to the end, as if this relation were the very essence of the constitution of the cell; as if, if I may quote words I used some years ago, fats were as indispensably built into the most intimate organisation of living matter as proteins themselves.[2]

From time to time biologists have recalled to mind the remark of Hoppe Seyler, made in 1866, that lecithine and cholesterol occur in every animal and vegetable cell, as well as the observations of Hermann recorded in the same year that the aliphatic narcotics, alcohol, ether, chloroform, all of them liberate hæmoglobin from the blood corpuscles. This property he considered, like their narcotic action, to be the result of their solvent power for cholesterol and lecithine, substances which he had recently shown to be present in the corpuscles. You will remember that Hans Meyer in 1899, and about the same time Overton, were among those on whom these early observations were not lost. Meyer clearly lays it down that the action of the substances he investigated proved for him that fats enter into the chemical structure of the cells on which these substances act, and that in this structure they are the seat of its functions. Overton's conception of the lipoid cell membrane was recognised as coming very near the truth, though the expression that he gave to it has not been in that form generally acceptable.

CHEMISTRY OF FATTY COMPOUNDS.

One of the reasons why progress in this direction has been and is likely still to be slow is the extreme difficulty that is presented by the more complex compounds of fatty acids as subjects of study and investigation. An important step forward has, however, been made, inasmuch as their chemical nature has been cleared up. By the work of H. MacLean,[3] Parnas,[4] and most recently Levene,[5] it is possible to obtain lecithine pure. The difficulty experienced by earlier workers has been shown to be due in part to the association with it of cephaline, in which an organic primary amine takes the place of the quaternary choline in lecithine. Levene has also defined the constitution of the third phospholipine sphingomyeline. He has, moreover, given good reason for believing that these three are the only such compounds that exist. Sphingomyeline introduces, however, complications. Into its composition there enter groups which, while clearly related to the known fatty acids, are not so familiar as those in lecithine and cephaline. But these groups occur also associated with galactose, instead of phosphoric acid and choline, in the galactolipines or cerebrosides.

So far as the pure chemistry of these substances is concerned therefore, the first steps, those that cost most, have been taken and a secure foothold obtained. But if we provisionally take the position to which A. Mayer and Schaeffer have advanced, if we regard the fat in cells as no less concerned with the structural organisation of cell substance than the proteins themselves, does what we know at present help us to form clear ideas of the relationship in that structure between the different constituents? It must be admitted that it is not yet sufficient for that.

PHYSICAL STATE OF CELL FAT.

There are two commonly current conceptions of the physical state of the fat in cells, for each of which there is foundation in familiar facts. We are led by one group of facts to think of it as enclosed in the liquid cell substance, by another to think of it as surrounding this cell substance as it were in a membrane. Microscopic observations reveal fat in connective tissue corpuscles as a mass included in the cell, distending it so that it is merely a protoplasmic receptacle for oil. The signet ring cells seen occasionally in the liver are in a lesser degree essentially the same. In other cells it is not uncommon to see a number of smaller drops included in the cell fluid, which in optical behaviour, solubility, and staining properties are unmistakably drops of oil. In many more, some would say by generalisation in all normal cells, much finer particles, the mitochondria of Benda or granules of Altmann, are recognisable, and these, too, may be shown by their solubility and behaviour with fixing reagents and with dyes, though with somewhat more difficulty, to be also fatty in nature. Fauré-Fremiet and Mayer,[6] and Mayer, Rathery and Schaeffer [7] have shown that the granules in the kidney and liver behave with solvents and with oxidising fixative fluids as if they contained unsaturated fatty acids which oxidation converts into hydroxy acids.

Similar fatty inclusions have been brought into view in tissues such as the normal heart and voluntary muscle-fibres stained with Sudan III. after the use of similar fixing fluids (E. T. Bell, 1912)[8] and with alkaline Scharlach R. solution after fixing with neutral formalin (Hays Bullard, 1916).[9]

Beyond this state of subdivision and dispersion histology cannot follow the fat in cells. But it is a well-known fact that cells in which it is easy to detect by histological methods fatty material in comparatively gross droplets do not necessarily contain any more fat than those in which the ordinary technique fails to reveal any at all. In the normal heart of guinea-pigs no fat can be detected by a technique which 24 hours after a dose of diphtheria toxin shows the guinea-pig's heart to be loaded with fatty droplets, and yet such heart muscle may be shown to contain no more fat than the normal control.[10] The toxin has set up changes in the physical state of the fat for which the name phanerosis has been proposed: the fat has been unmasked.

In the blood plasma fat appears to be, in part at least, in a state of subdivision too fine to be revealed by anything but the ultra-microscope. Ultra-microscopic particles have been described which are present in the plasma of animals, during the absorption of fat and at times when, as during the later stages of pregnancy, the transport of fat from the connective tissues is active; these particles are not visible at other times.

In observations such as these we have a series of gradations in the size of the fatty inclusions in cell protoplasm ranging from a drop that usurps almost the whole volume of a bulging cell to particles many hundred times smaller, less than $1\ \mu$ in diameter, and even by inference to particles smaller still, too small to take stain, or at any rate too small to be seen if they do. But in all the fat is enclosed in the cell fluid, more or less dispersed, more or less aggregated in it. We are led to speak of protoplasm as an emulsion of oily material in a watery medium sometimes too fine to be recognised, at other times more coarsely aggregated.

CELL MEMBRANE AND ITS PERMEABILITY.

That is one group of facts. The other is less objectively obvious and more inferential. It has gathered round the original observation of Hermann that the red blood corpuscles contain lecithine and cholesterol, and that solvents for these substances cause the hæmoglobin to escape from the corpuscles. Hans Meyer and Overton added other observations already referred to, and for nearly a quarter of a century there has been current a conception of cell protoplasm as enclosed in a fatty pellicle or lipoid membrane, which is the exact converse of the one that we have just been following out.

That an envelope with remarkable tenacity invests the red blood corpuscle is almost irresistibly conveyed by the moving photographs taken by Krogh and reproduced in his book on the "Physiology of the Capillaries." A frog's blood corpuscle is shown caught on the edge of the bifurcation of a vessel, which it rides like a sack of meal hung across a fence; later it can be seen gradually slipping over on to one side and then resuming its normal shape as it passes on. Almost all the facts of hæmolysis seem to require for their interpretation the existence of such a sac. This and the familiar behaviour of the red blood corpuscle to ether, chloroform, bile salts, saponine and soap solutions is the real reason for the acceptability of the theory of the lipoid membrane. Overton added to these his contributions on the permeability of cells in general: the surface membrane, he argued, must be of some lipoid material since the substances that could penetrate it were those which were soluble in lipoids. Ammonia, urea, acids like acetic, and basic dyes penetrate the cell membrane, and they are soluble in benzene and in substances that are like lipoids in that they will dissolve them; whereas sodium, sugar, amino acids, inorganic acids and salts, and acid dyes, which are not soluble in benzene, do not either penetrate. Hans Meyer's observations on the narcotic action of a variety of unrelated compounds which he found exerted their narcotic action in proportion to their partition-coefficient as between oil and water, were correlated with Overton's and interpreted as confirming them. Substances that will pass from water into oil will penetrate a lipoid membrane, and because certain substances suspend the activity of cells in proportion as they pass from water to oil they must be able to reach the cell because its surface is composed of material akin to oil; that was the implied argument.

This argument has been subjected to much criticism. The case of the dyes was specially taken up by Loewe, who showed that the dyes which penetrated the cell were not really soluble in lipoids; the proportion in which they are taken up by lipoids from watery solutions does not vary directly with the concentration of the solutions; proportionally more is taken up the weaker these are; in other words, it is not a case of partition between two rival solvents, but of adsorption, and if that is so a lipoid membrane would not account for the penetration of the dye into the enclosed aqueous protoplasm; it would, indeed, rather hinder it.

Moreover, the impermeablity of cells is not fixed and constant. For the life of cells it is essential that sugar, amino acids, even inorganic salts should be able to reach them. This is to some extent true even of the red blood corpuscle. A lipoid membrane characterised by unconditional impermeability to these substances would be fatal. Changes in permeability are in fact characteristic of the active cell. Excitation is accompanied by an increased permeability and the escape of ions which at other times are confined. The paralytic action of narcotic drugs is due to the fact that so far from increasing permeability, as solvents for a lipoid membrane would be expected to do, they diminish it. They paralyse because they prevent the increase of permeability that is inseparable from excitation. If they are present in fatal amounts then they do not merely narcotise the cell, but destroy all the properties alike which are characteristic of it when alive.

The lipoid membrane in the shape in which it was first propounded, perhaps in that in which it is still often thought of, is too crude to meet the requirements. Perhaps the simplest and not the least effective criticism of it is this. Almost every cell is and must be permeable to water: the lipoid membrane is by definition one that gives passage only to what is soluble in lipoids. It is difficult, of course, to say what is included and what is not included by the word lipoid, what the properties of lipoids are and what they are not. The term lipoid survives because it is convenient not to have to define it. Lipoids are apparently substances that have any of the properties of oil so long as they do not have them all. It may be unreasonable, therefore, to insist that the lipoid membrane ought to be impermeable to water; it is not unreasonable to expect some comment on the fact that it is always permeable to it. To say merely that the properties of lecithine are different from those of simple fats is not enough.

But the fact remains that the hæmoglobin is contained within the red blood corpuscle by something which behaves in many ways as if it were lipoid, had, that is to say, some of the properties of fat and not others. A considerable part of the stroma consists of lecithine at any rate, together with an amount of cholesterol that varies in different species of animals, and varies, too, directly with the power of resisting the lytic action of saponin against which cholesterol is known to give protection. The fact remains, too, that if these are the substances that contain the hæmoglobin within the corpuscle, lecithine and other compounds of fatty acids and also cholesterol are present in much larger quantities in other cells than in these, five or six times the amount, and that the permeability of other cells presents features of similarity with that of the red blood corpuscle. In fact the lipoid membrane remains, in some form.

Fatty and Other Constituents of Cells in Relation to Protoplasmic Structure.

These two contrasted groups of facts with regard to the physical relation of the fatty constituents of cell substance to the rest of its components, those pointing to the suspension of drops or droplets in a watery medium and those pointing to the cell contents being enclosed in a fatty pellicle, require to be brought into harmony with one another.

It is sometimes done in this way. Fatty substances sufficiently subdivided and dispersed in a watery medium are supposed to behave as if they formed a colloidal solution of the type described as emulsoid. It is characteristic of the most familiar of such solutions that they have a lower surface tension than the pure solvent, and that consequently the substance lowering surface tension is concentrated in the surface. All proteins so far as is known are concentrated in the surface of their solutions, in the case of some to such a degree as to form a coherent solid film there. It is accordingly common to suppose that fatty substances will be similarly concentrated in the surface of cells in which they are dispersed.

But an emulsoid solution according to the accepted idea consists of aggregates, which are so constructed as to contain some of the solvent, and which are dispersed in a continuum of the solvent containing some of the dispersed phase in true solution. The structure of the aggregates is not understood, but may be supposed to consist in the binding of molecules together by polar affinities in such a way as to leave interstices capable of accommodating relatively large quantities of water; a jelly may contain 98 per cent. of water. The solvent then permeates the interstices in these aggregates, where it must be supposed to be entangled so as to lose some of the freedom of an unencumbered liquid; but even in these interstices it is continuous with the surrounding body of fluid that has lost none of this freedom. This fluid outside the aggregates contains sparse molecules of the solute, which since they lower its surface tension tend to concentrate in the surface.

But fatty substances are immiscible with water. Emulsions of immiscible liquids are not the same as emulsoid solutions. They behave rather as suspensions of insoluble solids. The fact that two liquids are immiscible precludes the possibility of molecular dispersion. If a colloidal solution of one in the other is obtained that solution must be of the nature of a suspension, a suspensoid colloidal solution, quite different from the "hydrophile" emulsoid system. Moreover, the dispersion will be unstable and the droplets will tend to coalesce and run together; because whenever they come within a certain distance of one another, less than the diameter of the sphere of molecular attractions between the molecules of the solvent, the cohesive forces among these latter molecules will drive the globules into one another by pulling the solvent aside from between them. Such emulsions are stable only if there is some substance dissolved in the solvent that lowers its surface tension and concentrates on the interface. For two droplets of the emulsified liquid then to coalesce, the interfacial area must be diminished and some of the adsorbed molecules be driven back into the solution, and that is resisted by the cohesive forces between the molecules of the solvent.

It is true that fat droplets, as any foreign bodies or molecules which attract and are attracted by the molecules of water less than the molecules of water attract each other, will tend to be squeezed out on to the surface whenever they come within a certain distance of it, a distance less than the radius of the sphere of attractions between water molecules.

But to explain the formation of the membranes investing cells in this way is almost like supposing that the sea is kept within its bounds by the driftwood it washes up on to the shore. That which invests the surface of cells is too highly organised, has properties of specific permeability and impermeability far too delicately balanced to be the product merely of undiscriminating processes such as these. Moreover, a cell is an aqueous system surrounded by an aqueous system; to suppose that the limiting membrane is formed by adsorption at the interface begs the question; there is no continuous interface till the formation of a coherent membrane brings it into existence.

There is another way in which the coexistence of continuous membranes and dispersed aggregates may be understood which is based upon the observation of Bancroft and of Clowes.[11] Oil is easily emulsified in an aqueous solution of alkaline soaps. If these soaps are converted into the calcium soaps, which are insoluble in the water, but soluble in the oil, the drops of oil join up to form continuous layers enclosing the water. What was the dispersed phase becomes the continuous one, and vice versa. By inversion of phases the emulsion becomes one of water in oil. It is thought that in the unhomogeneous system of the cell there may be at the surface an emulsion of this description, of water in oil in some parts or at some times, and in other parts or at other times possibly one of oil in water.

Some shadow of support for such a conception is perhaps suggested by the well-known facts as to the influence of calcium and of sodium on the permeability of cells. A tissue of cells has a low conductivity for electric currents. The ions that could conduct are confined within the impermeable cell membranes and by this restriction of their movements are prevented from conducting the current. For this normal impermeable condition of membranes calcium has to be present; the same tissue acquires the power of conducting, allows, that is, freer passage to the ions, when by means of solutions of sodium salts free from calcium the normal proportion between sodium and calcium ions in the surface is disturbed; and the normal state of the surface membrane can then be restored when a proper proportion of calcium is added to the solution.

As a result of this review of current conceptions as to the relation between the fatty and other constituents of cells in the structure of their protoplasm, I think it must be admitted that there is room for further work and for data obtained in other ways. Some such data have begun to be available, and I propose to inquire how far they may be helpful.

An Address

ON

ARTHRITIS IN CHILDHOOD.

Delivered at the Children's Hospital, Feb. 26th, 1925,

BY F. JOHN POYNTON, M.D., F.R.C.P. LOND.,

PHYSICIAN TO UNIVERSITY COLLEGE HOSPITAL AND THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET.

ARTHRITIS occurring in childhood presents various aspects of interest, and is an admirable introduction to the more complex problem of arthritis in adult life. We must recognise that the joints reach great perfection in childhood, and no one can see their wonderful mobility and, if middle-aged, recognise the loss of that advantage without being convinced of this fact. High efficiency means healthy structure, and this in turn is usually resistant to disease. Be that as it may, in this hospital, apart from tuberculosis, a severe arthritis is comparatively infrequent, and those who have studied it at all ages must be struck by the absence in the young of those degenerative factors which make this condition in the elderly often so crippling, as is exemplified by osteo-arthritis of the hip-joint.

In adult life we are continually in perplexity as to how much importance should be attached to metabolic faults, nerve degeneration, and traumatic factors. On the other hand, in both young and old, the "local focus" is now to the fore, but it is remarkable how often in adult rheumatoid arthritis we fail to detect any convincing evidence of a local focus, however much we may suspect its presence.

In childhood, with few exceptions, we can clearly trace the factor of infection. It is sufficient for me to recall to memory tuberculous, rheumatic, syphilitic, and gonococcal arthritis, influenzal, pneumococcal, meningococcal, and typhoid arthritis, and the septic staphylococcal and streptococcal forms. There are, nevertheless, as in the adult some mysterious cases, variously termed Still's disease or rheumatoid arthritis, and some remarkable examples of osteo-arthritis. But we cannot but feel, when we consider the cases of Still's disease, that they must also be infective in origin when we recall the fever, the enlarged glands and spleen, the sweating, and general toxæmia.

From this broad survey we learn some useful lessons. Almost every example I have just quoted is an instance of one manifestation of a general disease, and if we can hope to solve such a problem as the pathology of arthritis it must be from a study of all the other manifestations of these causal diseases, any one of which may throw a side light on the difficulties of the particular symptom "arthritis." This warns us against a too narrow specialism. Then, seeing the importance of infection in the arthritis of childhood, we can in these young children learn much about the results of such infections without complicating our survey, as in the adult, with degenerative and other secondary factors. Though, however, we must be on guard against too narrow a specialism, there can be no doubt that the detailed study of the structures involved in an arthritis is essential. This will include the synovial membranes, the cartilages, the bones, ligaments and capsules, the circulation and nervous supply, the tendons, bursæ, and the skin itself. In the child, too, we must remember also the epiphyses, for otherwise we may mistake an osteo-myelitis for a primary arthritis.

I will give some illustrations of the importance of this detailed study. A child may suffer much pain with no obvious swelling of the joints, the cause lying in the tendons around or in the nerves supplying the articulation; this is not infrequent in acute rheumatism. On the other hand, we sometimes find in acute rheumatism both knee-joints distended with fluid, and yet the child does not complain of pain. In other cases spasm of the powerful hamstring muscles may produce in the course of a stubborn but not necessarily crippling arthritis of the knee-joint early flexion. Almost before we are alive to the danger we may find ourselves confronted with the problem of correcting this flexion, for otherwise there will follow adhesions, and then the child will have to endure the trial of such painful manipulations as may be necessary to break them down. In the destructive forms of arthritis the erosion of the internal ligaments of the knee-joints may lead to backward dislocation or, more distressing still, insufficient care with manipulative movements may precipitate this result by actually tearing them. I need not dwell upon the recognition of "starting" pains, or the presence of abscesses in connexion with the joints. There are also rare and curious cases of chronic arthritis associated with scleroderma, in which the closest attention has to be directed to the skin over the affected elbow-joints, which may become as thin as tissue-paper, and then liable to ulcerate and cause troublesome sores.

TUBERCULOUS ARTHRITIS.

It would be unnecessary for me to give a description of the classical tuberculous arthritis, but I will touch upon some of the more unusual results.

Poncet, in 1897, described a "tuberculous rheumatism," meaning by this an arthritis which closely resembled in its features rheumatoid arthritis.

Since the date of that paper I have been always on the watch for such cases. That acute tuberculous polyarthritis may occur in children is certain, and you may easily mistake it for acute rheumatism, but as I have seen on more than one occasion the child may die of tuberculous meningitis. It has been suggested that the chronic arthritis of the Still type is tuberculous, but all our evidence here I believe, including the necropsies, appears to negative this, and in the considerable number that I have seen I have never detected a tuberculous origin. The tuberculous rheumatism described by Poncet accordingly appears to be a rare occurrence, though I am quite prepared to admit that this is only a local experience. Dr. L. Findlay, in 1920, published three cases, one of them dying of tuberculous meningitis.[1] Mr. Lusné reported in Paris a case of an infant of 13 months with rheumatoid arthritis and a positive von Pirquet reaction, who died at the age of 3 years from tuberculous meningitis, and both of whose parents were consumptive. Accordingly at present I keep an open mind upon the frequency of "tuberculous rheumatism."

If "tuberculous arthritis" may be mistaken for the rheumatic, so sometimes may the rheumatic be mistaken for the tuberculous. I have seen a boy who had been put on his back in a Phelps's box for two years on account of a suspected spinal caries. It was, as a matter of fact, a rheumatic arthritis of the cervical spine. Although he had been kept at complete rest during this time he suffered from two attacks of rheumatic heart disease, the second being a severe pericarditis with much valvular damage. A rheumatic stiff neck may give trouble for weeks, although we associate it as a rule with a sudden onset, much pain, and swift recovery.

STILL'S DISEASE.

I come next to Still's disease, and call it by that name because I think it will define the particular group as it was first described by my colleague. I was fortunate to see many of the original cases upon which his classical paper was based.

The chief characteristics are: (1) An onset which is almost always before the second dentition. (2) The female sex is more often affected than the male. (3) The cause is unknown. One factor which has attracted me is the fact that several of my cases have come from low-lying and damp situations. (4) The articulations, apart from the thickened and vascular synovial membranes and ligaments, show little change. In some long-standing cases the synovial membrane has eroded small pits in the periphery of the cartilages, and there may be some fibrous adhesions, but there are no osteophytes, and there is no eburnation of the bones. The pitting of the cartilage by adherence of the synovial membranes resembles precisely the condition I have seen in experimental arthritis produced by the intravenous injection of streptococci. (5) The lymphatic glands and spleen, which are enlarged, show little change in structure, though there may be small hæmorrhages.

I have myself only seen one case from its very commencement, and I give a few details of this illness because they are of interest.

L. B. M. was admitted on August 2nd, 1923, for difficulty of breathing and pains all over the body which, with fever, had been present for three weeks. There were also night sweats and anorexia, and swelling of the wrist-joints. There was no family history of rheumatism. The child was pale and fretful. The lymphatic glands and spleen were palpable, the wrist-joints were swollen, and the temperature 100° F. The heart was enlarged, but there was no valvular disease. The count of the white blood-corpuscles was 75,800 per c.mm. The temperature remained raised for two months, and the feet and ankles became affected; later the knees also became swollen and the neck very stiff. In January, 1924, he had some bronchitis.

One can hardly doubt that this must have been an infective process, and the quick breathing at first raised the suspicion of broncho-pneumonia, but this never developed.

As a rule the onset of the disease is gradual, with stiffness of some of the joints as an early symptom. The knees, the wrists, and the cervical spine are first affected, and the changes involve the capsules of the joints and not the bones; and there is but little fluid exudation and that viscous and clear. The hands and fingers are soon implicated, and the ankles and feet may also soon be attacked. The child has outbursts of pain such as occur in the rheumatoid arthritis of adults. This disease is polyarticular and remarkably symmetrical in its distribution, with great tendency to early contractures and rigidity. The lymphatic glands are enlarged in association with the joints that are affected; they are not, as a rule, tender and never suppurate, but they may reach a considerable size, and even in some cases can be demonstrated in a photograph. The spleen may extend one or two inches below the costal arch but, as it tends to shrink again in the quiescent stage, this enlargement must be sought for during the more acute phase. Valvular lesions are not found, but in a few cases a film-like pericarditis and pleurisy have been discovered after death. There may be some exophthalmos and occasionally jaundice, and the temperature in severe cases is high and swinging between 100° and 104° F., and then the child may have severe sweatings and be extremely ill.

One of the most distressing features is the painful stiffness of the neck; as a result of this there may be noticed a striking over-action of the frontalis muscle when the child looks upwards. The course of the disease is marked by periodical outbursts of activity. Some of these children have bad teeth, others nasal discharges, but although treatment for such should at once be carried out I must confess that I have seen little direct result from these steps.

In common with other observers I have met with a considerable number of cases that do not coincide with the classical description, but which nevertheless show certain features that lead one to include them in this group. Some of these have been remarkable, and one in particular impressed itself on my memory.

This was a boy who showed an arthritis and fever with enlarged glands, but no splenic enlargement was discovered. The course of the disease in hospital was so disastrous that the parents removed the boy in disgust. For a year I saw nothing of him, but one day the father brought him up to my out-patient department. He had made a marvellous recovery, although his knees, elbows, and neck were stiff. This improvement had commenced about three months after leaving the hospital, and the only medical treatment had been cod-liver oil. I saw him once more six months later when he was again very ill. His chin now nearly touched his sternum and this is the remarkable feature: his heart was greatly enlarged, and there was a loud systolic mitral murmur and an enlarged liver with dropsy and pulmonary œdema. His parents would not leave him, and I had little doubt he died from cardiac failure, but the war supervening I lost sight of him.

Other cases in turn may show no enlargement of the glands, but the arthritic condition resembles that of Still's disease. I have made, over a good many years, with skilled assistance bacteriological examinations of several of these cases. The arthritic exudations, the blood, and in some cases the lymphatic glands, have been removed during life. The results have either been negative or, if micrococci had been isolated, they have not been demonstrated, or reproduced the disease. The fluid obtained from such joints has been in my cases scanty and viscous. The lymphatic glands, as we must remember, are not destroyed by the disease, and one suspects that the infective agent if it is present in them is taken up by the tissue cells, and one feels that unless an exactly suitable culture medium were used that they would be unlikely to survive their transference to the altered surroundings. All the examinations of the blood have been negative, though there may be an increase in the number of polymorphonuclear leucocytes.

OSTEO-ARTHRITIS.

Osteo-arthritis in childhood—by which I mean a chronic arthritis with hypertrophic changes in the synovial membranes, ulceration of the cartilages and osteophytic formation leading to bony thickenings and out-growth—is a very rare occurrence in the hospital, and, though of much interest, a subject upon which it is difficult to obtain information. In adult life it is the general experience that this form of arthritis usually commences later than the rheumatoid, and if we couple this with its apparent rarity in childhood it leads one to suspect that degenerative changes must be a factor in its development.

One of the most instructive cases of this type was shown by Mr. P. Turner in 1908 at the Society of Study for Disease of Children.

This was a girl of 10, both of whose knee-joints were distended with fluid, and thickened synovial membrane which, on each side of the patella, could be rolled under the fingers. There was slight grating on flexion of the knee-joints, and the ends of the bones appeared to be thickened. The wrist-joints and the first interphalangeal joints were also affected. There was this unusual feature, the absence of pain. That the lesions were osteo-arthritic in type was undoubted, but it was not absolutely clear that the cause was not syphilitic or tuberculous.

In my experience it is not a very rare event in a severe chronic arthritis in childhood to find spindle-shaped swelling of the fingers, Heberden's nodes, and some grating on movement of the interphalangeal joints. In 1919 Dr. R. Armstrong described such an occurrence in a boy of 12 years and his sister of 11. In the boy's case the illness had commenced at 4 years of age, and in 1918 there was a rheumatic attack with swelling of the ankles and knees. Dr. Armstrong had plotted out a pedigree showing the familial nature of this disorder, and as no local focus was apparent inclined to the explanation of the condition as one of a pure degeneration. Others were in agreement with him, but I am not yet prepared to go further than to accept a tissue tendency to some rheumatic infection. When you recall what I have already said of osteo-arthritis in the adult you will appreciate the interest there is in finding the term "degeneration" appearing in the pathology of the condition in childhood.

Mr. L. Barrington-Ward, in THE LANCET (1912, i., 157) under the title of Double Coxa Vara with other Deformities occurring in brother and sister, described two remarkable cases which I had seen myself on one occasion. The diagnosis raised such questions as Still's disease, osteo-arthritis, congenital syphilis, achondroplasia, and congenital abnormalities.

PNEUMOCOCCAL ARTHRITIS.

Passing now to pneumococcal arthritis, this again would appear to be in our medical wards a very rare event, and perhaps this is somewhat surprising, for about 70 per cent. of such cases are associated with pneumonia. It is needless to say that we get many cases of pneumonia and broncho-pneumonia, and we also get empyema and more rarely suppurative meningitis and pericarditis of pneumococcal origin. If we had cases of suppurative and non-suppurative arthritis complicating our cases of pneumonia I believe we should note them. Yet I cannot recall one case during my five years' tenure of the wards. That some of the mysterious cases of arthritis I have associated in my mind with Still's disease were due to pneumococcal infection is possible, but none of them has been ushered in to my knowledge by a frank pneumonia. As I shall mention later, there have been five examples of this arthritis occurring in surgical wards which have been accurately determined by culture. Three of these occurred in infancy, but none commenced with a pneumonia but appeared to be incidents in a general infection. As a rule one joint is attacked, and the order of frequency is the knee, the shoulder, the hip, the wrist, the ankle, the elbow, and the sterno-clavicular joint. The proportion of suppurative to serous cases is about 10 to 1.

Dr. Cave, of Bath, was the first in this country to demonstrate the exact nature of this form of arthritis, and his paper interested me at that time (1901) because then, when working at rheumatism Dr. A. Paine had isolated the pneumococcus from a doubtful case of arthritis, and this enabled us to recognise at once the importance of Dr. Cave's observations.

BACTERIOLOGICAL INVESTIGATIONS OF ARTHRITIS.
By DR. D. NABARRO.

At this point it will be convenient to give some interesting details on the bacteriology of arthritis, for which I am indebted to Dr. Nabarro from the Research Department of the Hospital for Sick Children. They are concerned with the result of the examination of the exudations obtained from the joints of 108 cases of arthritis between 1917 and 1924.

In 54 of these the tubercle bacillus was found, or the case on clinical and cytological grounds was most probably tuberculous. Fifty-four were non-tuberculous.

In 21, streptococci were isolated and grown.
,, 11, staphylococci ,, ,, ,,
,, 11, the exudation was sterile.
,, 5, the pneumococcus was isolated and grown.
,, 3, the influenza bacillus ,, ,, ,,
,, 1, staphylococci and streptococci were isolated and grown.
,, 1, the *Staphylococcus albus* and *citreus* were found.
,, 1, a Gram-negative bacillus (unidentified) was found.

You will see from these numbers—only five examples in seven years—how rarely the pneumococcus has been isolated from the joints of children under 12 years. That there have been some examples in which examination was not made is quite possible.

The age incidence of the non-tuberculous cases was as follows. There were 49 records, some of the 54 cases having been twice investigated.

17 were under the age of 1 years.
8 were from 1 to 2 years of age.
3 ,, ,, 2 to 3 ,, ,,
2 ,, ,, 3 to 4 ,, ,,
4 ,, ,, 4 to 5 ,, ,,
5 ,, ,, 5 to 6 ,, ,,
3 ,, ,, 6 to 7 ,, ,,
5 ,, ,, 7 to 8 ,, ,,
0 ,, ,, 8 to 9 ,, ,,
1 ,, ,, 9 to 10 ,, ,,
1 ,, ,, 10 to 11 ,, ,,
0 ,, ,, 11 to 12 ,, ,,

More than half these cases, it will be seen, were under 2 years of age. Eleven were streptococcal and five staphylococcal, three pneumococcal, three influenzal, two were sterile, and one was possibly gonococcal, but the report was doubtful. It is interesting to find that there was not a single case of meningococcal arthritis.

GONOCOCCAL ARTHRITIS.

Gonococcal arthritis is a very rare experience here, and only one doubtful case is recorded by Dr. Nabarro. Clement Lucas, in 1885, described its occurrence in infancy in a case which was of considerable interest, because then the bacteriological features were not known. Nevertheless the case was a convincing one because the mother had been infected 14 days before confinement, and there was acute vaginitis. Her husband was under treatment at the time. The infant on the second day had severe conjunctivitis, and about the fourteenth day developed arthritis of the left knee and the left wrist. The ophthalmia was treated and the arthritis gradually subsided under treatment which was of the simplest. Without the application of a splint or giving of medicine a cooling lotion was sufficient to bring about a good recovery.

CONGENITAL SYPHILIS.

As is well known, congenital syphilis frequently affects the bones and cartilages and may also cause arthritis. The osteo-periostitis of infancy (one of the causes of pseudo-paralysis) is essentially an epiphysitis with periostitis of varying degree. Radiography demonstrates these lesions very clearly. The joints themselves in the neighbourhood of the epiphyses may be implicated and the synovial membranes swollen.

Equally characteristic, but not so often seen here, is the arthritis that occurs in older children. This we associate with such other late congenital lesions as Hutchinson's teeth, interstitial keratitis, and deafness. In some cases there may be an acute synovitis with fever, pain, and swelling; in other cases an osteo-arthritis with destruction of cartilage and bone, and the formation of osteophytes. The best defined cases are those in which both knee-joints are attacked and show large, puffy, almost painless swellings which fail to react to any treatment until the true cause is discovered. The diagnosis from tuberculous arthritis may be difficult, but the other stigmata of the disease and the blood reaction usually give the key to the solution.

INFLUENZAL ARTHRITIS.

As recently as October, 1924, Dr. Nabarro and Mr. J. F. H. Stallman[2] published a record of three cases of influenzal arthritis occurring in infancy. To those who are interested in the arthritis of adult life these exact records must be valuable, for they will recall how often in cases of rheumatoid arthritis a serious advance in the disease may follow an attack of severe influenza. Here we have proof that the influenzal infection itself may attack the joints of children. In these three infants the arthritis affected in each case the knee-joint. The exudations were purulent and the Gram-negative bacilli were present in numbers and were both extra- and intra-cellular. Two of the cases recovered and the final results were good. One died of influenzal meningitis, but the arthritis in this case also was running a favourable course. The writers, however, point out that in some of the recorded cases there has been total disorganisation of the joints affected. The treatment of these three cases was surgical.

ARTHRITIS AND MUMPS.

From time to time when investigating the history of acute rheumatism in childhood I have come upon a certain number of cases of heart disease which have been dated from an attack of mumps. I have never had the opportunity of tracing the development of this heart disease, and though I have heard of cases of arthritis following mumps I have never actually seen the condition. However, in THE LANCET of Jan. 10th, 1925, p. 86, there is an abstract from a thesis by Dr. P. Maisondieu upon this subject. He calculates the frequency of its occurrence at just under 0·5 per cent. It is usually a late manifestation, commencing about 14 days after the disappearance of the parotitis, and it may synchronise with an attack of orchitis. The distribution is as a rule monarticular, thence spreading sometimes from one joint to another. There may be much pain and swelling, or again there may be pain in several joints but no swelling. Suppuration is the exception. The temperature may be slightly raised and the duration of a prolonged attack extend over five or six weeks.

HÆMOPHILIC ARTHRITIS.

Hæmophilic arthritis is very uncommon in the medical wards, but I have seen a few severe examples and they present some striking features. One of the most obvious is the acute onset with intense pain; another is the remarkable recovery that may occur in the joints, which again and again seem as it were to rebound from the sudden injury to their structure. Nevertheless we find that there will eventually arise an increasing disability, at first from stiffness, later from more serious damage of the type of an osteo-arthritis as many years ago Sir Anthony Bowlby pointed out to us. The knees are the joints most often attacked and eventually severe crippling and ankylosis result.

Another interesting point is the periodicity of the attacks. Possibly you may be under the impression that the hæmorrhages in these cases are invariably the result of some injury. We must admit that it is difficult to exclude this possibility, but the strange feature is that a definite injury may at one time of the year produce no effect, when at another, as a result of the slightest slip or twist or indeed without any remembered event of this kind, a severe effusion may develop. This is one of the terrors of the disease, for the patient lives as it were with the sword of Damocles suspended over his head. Parents will tell you of certain warnings which show that the mysterious change in the blood is developing; they will tell you of nervousness, irritability, and languor, of headaches, and even of uncomfortable sensations of tenseness in the joints. It is remarkable in the history of blood disorders how often we meet with this periodicity, and you need only recall the rise and wane of leukæmias, of lymphadenoma, of anæmia gravis, and purpura hæmorrhagica as striking instances. The occurrence of high fever and pericarditis during one of these attacks as I have seen leads one to speculate whether an infection, possibly even that of an ordinary cold, may not originate these hæmorrhages by producing the mysterious change in the blood which causes the bleeding.

As a rule the diagnosis is not difficult, for we have so frequently a previous history of bleeding either in the patient or in his forbears, and the intense rapidity of the onset, the pain, and the discoloration of the skin round the joint usually also guide us aright.

The treatment is difficult, and many remedies have been used. Calcium lactate combined with magnesium carbonate in 20 gr. doses are sometimes given an hour before meals. Dr. Lovell Gulland has found fresh serum most useful. Horse serum may be used either by the mouth or intravenously in 10 c.cm. doses. The ordinary horse serum which you obtain from manufacturing chemists is of value, and Dr. Gulland has found that the effect lasts about a month and has used with good result prophylactic doses given once every four weeks. You may speculate as to the danger of anaphylaxis, but in his experience the risk is slight, and can be obviated by a small preliminary injection when from the time interval you suspect this danger.

ARTHRITIS AND SCLERODERMIA.

There is a very unusual form of arthritis met with in children and young adolescents which is associated with sclerodermia and Raynaud phenomena. The appearances of these cases is remarkable, for their skin is like leather and cannot be picked up from the hardened and atrophied muscles below. The trunk and the extremities may be affected and the articulations are stiff from the induration of their ligaments; the hands and feet appear withered, and attacks of cyanosis may occur accompanied by acute pain. Over the elbows the skin becomes reddened and so thin that the bones seem ready to break through. To a lesser degree there is the same appearance over the knee-joints. In some instances the skin over the elbows shows a chronic dermatitis and, giving way, fissures form which are very slow in healing.

The usual history of these cases is that there have been attacks of arthritis—or as they are termed "rheumatism"—and that these have gradually increased in gravity and duration. I have never myself seen a case in which the joints have shown any effusion, but they have been invariably stiff and shrunken and the skin over them shiny and a dull-red colour. As you may imagine, the treatment is most discouraging. Some improvement has been obtained with iodolysin combined with local treatment by radiant heat and inunction of oil, and together with these are combined skilled massage and manipulation. I have also seen psoriasis associated with these cases which has interested me, because I have noticed that this skin disease in the young not infrequently occurs in rheumatic cases that are subacute and liable to show unusual features.

---

[2] THE LANCET, 1924, ii., 743.

Raynaud phenomena are not confined to these rare cases, but in adult life may be met with in rheumatoid arthritis, and in a paper on "spasmodic symptoms in rheumatism" I have described their occurrence in the acute rheumatism of childhood. In such cases there has been an obvious attack of acute rheumatism with arthritis and valvular disease, and then some months or even a year later the hands and forearms may show the characteristic sudden cyanosis accompanied by intense pain. In these cases the condition has yielded to electrical treatment and massage, together with precautions against undue exposure to cold.

MYSTERIOUS ARTHRITIS.

There remain some mysterious cases of arthritis which are to me most perplexing, and I have been glad to find that my colleague, Mr. H. A. T. Fairbank, in his wide experience, has met with the same difficulty. It is in connexion with the hip-joint that I have met with these particulars. This, for example, is an instance :—

A rapidly growing boy of 14 years fell in a football scrummage with his right leg strongly abducted. At the time he had pain, but this passed off and remained absent for the rest of the day and during the night. The next day he had to stand in the train for a long time, and when walking in the afternoon began to feel discomfort in the joint. That night he woke with severe pain and his temperature was 102° F. Next day there was fullness over the hip-joint and great pain on movement. In this case there was no evidence of acute rheumatism, and the immediate fear was an acute epiphysitis. The late Mr. T. H. Kellock saw him with me in consultation and advised the policy of rest with close supervision, and agreed that there was an acute arthritis. The symptoms subsided and the temperature dropped slowly to normal, and a perfect recovery resulted.

Mr. Kellock at the time told me that he had seen several similar cases in growing boys. Such a condition as this coming on when an interval of time has elapsed after the probable injury—an interval during which there has been no apparent evidence from pain or limping of a direct reaction to injury—is always disquieting, and particularly if with the onset of the pain the boy, as in this case, looks ill and has definite fever. The possibility of an acute osteo-myelitis of the head of the femur must be a cause of great anxiety. There are, however, other cases of mysterious arthritis of the hip-joint with no history of injury. These may occur even in infancy, and if one can judge from their course are apparently not tuberculous in nature. Even if their course is not always favourable but leads to a destruction of the cartilage and erosion of the bones, still it does not resemble that of tuberculosis, but more closely the condition which we associate in adults with acute osteo-arthritis.

TREATMENT.

The treatment of arthritis in childhood rarely presents any special features from the medical aspect. Rheumatic arthritis is frequent, but with rest the rapid subsidence is remarkable, and we all know the value of the salicylate compounds for this symptom.

The problem in Still's disease is far different. Every sort of drug and treatment has been tried, but no one can claim any certain remedy. I think we should all agree that septic foci should receive treatment, but there has been no convincing evidence in my cases that as a result the disease has relented. On the other hand, I am certain that the milder forms with persistent treatment and careful nursing make very considerable improvement. At one time soured milk seemed to do good. Intestinal disinfectants, such as small doses of calomel or β-naphthol and such like, have never appeared to me to have any clearly defined success, and the same applies to renal disinfectants and vaccines. I have previously insisted on the importance of such an individual being rescued from damp and cold surroundings. How such surroundings alter the chemical processes of the human body I do not understand. But I believe that they so damage the connective tissue skeleton that an infection not necessarily massive or continuously supplied from a local focus and not necessarily of a peculiar virulence can produce profound disturbances which cannot be rectified because the power of resistance is deficient and the infection itself not destroyed. Of local remedies I have seen some benefit from the treatment by ultra-violet rays. There can, however, be little doubt, I think, that we are in the same difficulty with this disease as with the rheumatoid arthritis of adults.

A YEAR'S EXPERIENCE OF INSULIN.*

By J. K. RENNIE, *M.C.*, M.B., B.SC. GLASG.,
DISPENSARY PHYSICIAN, ROYAL INFIRMARY, GLASGOW.

THIS paper gives a brief report of the results obtained in the treatment of diabetes with insulin, in Dr. Cowan's wards, during the year March, 1923, to March, 1924. During this year 49 patients were admitted for treatment, and Table I. shows the age and sex incidence, and mortality among these cases :—

TABLE I.—*Incidence and Mortality.*

Age.	Male.	Deaths (to date).	Female.	Deaths.
1– 9	2	—	—	—
10–19	5	1	2	1
20–29	3	—	5	—
30–39	6	—	4	2
40–49	6	—	3	—
50–59	2	—	4	—
60–69	2	—	3	—
70–79	1	—	1	—
Total ..	27	1	22	3

Forty-nine cases, of whom four were dead before March 1st, 1924.

All were suffering from glycosuria, but the significance of this symptom varied as shown in Table IA.

TABLE IA.—*Variation in Incidence of Glycosuria.*

—	Male.	Female.	Total.
"Renal" cases	—	2	2
"Lag" cases	2	—	2
Not diabetic	2	3	5
Diabetic, but not suffering from diabetes	2	5	7
Diabetic, and suffering from diabetes	21	12	33

Diagnosis.

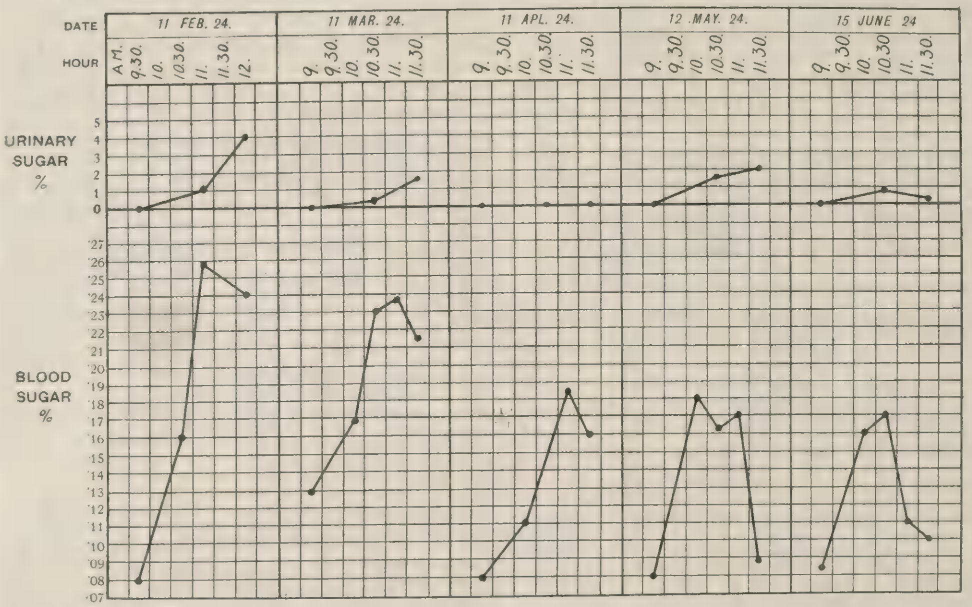
With regard to diagnosis, there is very general agreement that, particularly in the selection of cases for insulin, it is essential to discover whether or not one is dealing with a case of true diabetes. The method adopted to differentiate in doubtful cases was the "glucose test." Urinary analysis following the ingestion of glucose or other carbohydrate is not conclusive, though the presence of a trace of sugar in the urine after, say, 25 g. of glucose, unaltered in amount after 150 g. glucose, would certainly be very suggestive of a non-diabetic glycosuria; but by the glucose test only can a proper distinction be made with fair certainty. The two "renals" and two "lags" in this series were tested in this manner as were also the milder diabetics. In the more severe diabetics such a test was, of course, unnecessary. The results obtained from these and numerous other observations would seem to show that the information obtained from the glucose test is reliable in the great majority of cases, but the following cases are worthy of attention :—

---

* The expenses of this investigation were borne by the Medical Research Council and by a grant from a fund raised by Jas. Macfarlane, LL.D.

CASE 1.—M. L., a well-nourished girl of 15, was admitted on Feb. 5th, 1924, complaining of thirst and polyuria, which had come on suddenly three weeks before. She had been employed for six months in a baker's shop, and had eaten sweetened cakes in large numbers during that time. The family history was negative. The urine contained 3 per cent. sugar. Glucose tests were performed, as shown in Chart 1. The first test was made after a brief period of starvation, but from that time onward the diet remained constant at C. 80, P. 60, F. 120. The first and second glucose tests gave typical diabetic curves with urinary sugar results to correspond. The fourth and last tests give curves which, with the urinary sugar observations, would suggest a renal glycosuria.

CHART 1.



All tests were made in the early morning before any food had been taken.

CASE 2.—J. D., a boy, aged 6, was admitted to the wards on Sept. 7th, 1922, complaining of headache, thirst, and frequency of micturition of some 2½ months' duration. While in hospital there was never more than a trace of sugar in the urine, and his blood-sugar, with one exception, never exceeded 0·15 per cent. Chart 2 shows the result of a glucose test at this time. The first curve might be called a "lag," though no sugar was detected in the urine. Certainly the return of the blood-sugar to normal in 1½ hours is satisfactory. Less than a year later he was readmitted to hospital, and now insulin was necessary to keep the urine sugar-free. Curves 2 and 3 show the results of glucose tests at this time, and are clearly diabetic. The boy had not been kept on strict diet during the intervening period.

It would thus seem clear that it is dangerous to rely entirely upon the result of a *single* glucose test. Two or three observations should be made at intervals of some weeks, particularly in doubtful cases.

Treatment.

In view of the possibility of error, as shown in the results given above, the "renal" and "lag" cases were advised to refrain from obvious sugar, but no other limitation was placed upon their diet. The "not diabetic" cases, five in number, were patients admitted for treatment of some quite different disability in whom a glycosuria was discovered on routine examination of the urine. Three were old arterio-sclerotics; one man suffered from locomotor ataxia; and one was a woman of 47 with bronchitis, and a coli infection of the urinary tract. In all five the morning blood-sugar reading was normal. In these cases the glycosuria was transient, and disappeared quickly on a slightly modified carbohydrate diet with no severe restrictions. All these cases were instructed to return for observation, and many have been re-examined at an interval of three or four months to confirm the correctness of the diagnosis. The seven diabetics who showed no symptoms of diabetes save glycosuria were treated on the usual Allen lines, and all left hospital sugar-free on an adequate diet. It might be mentioned with regard to the "Allen" diets employed, that protein and fat were never so restricted as recommended in the earlier "Allen" treatment, the object being to render the patient's stay in hospital as brief as possible. Later, following the work of Newburgh and Marsh, most diet schemes have been modified in a similar manner—with perhaps a rather lower protein content—thus confirming the wisdom of the practice which we had adopted from a practical standpoint.

Of the patients who were suffering from diabetes two males and one female did not require insulin. Thirty of the 33 patients suffering from diabetes required treatment with insulin. Of these, 11 were given insulin at once on admission to hospital. These cases fall into two categories: (1) acid cases; (2) cases showing much emaciation, frequently with signs of cardiac failure.

(1) Eight cases showed severe acidosis. The first essential in these cases is to eliminate the acidosis, and to this end insulin was given in large amount together with a diet containing a considerable amount of carbohydrate. The largest dosage of insulin required in these cases was 70 units in the 24 hours, but in most cases 10–30 units in the 24 hours was sufficient. (Chart 3.) Various diets were experimented with, but an oatmeal diet with insulin appeared undoubtedly to be the most efficacious in rapidly clearing up the acidosis. The "oatmeal diet" employed was similar to that of Van Noorden save that eggs and butter were omitted; 300 g. of oatmeal were soaked in 3000 c.cm. of water, strained, then boiled for ten minutes, and 300 c.cm. of the resulting gruel were given two-hourly. The value of this diet was approximately C. 60, P. 12, F. 12. Opinion is divided as regards the advisability of giving sugar in these cases, and, as MacLean has pointed out, the blood-sugar is invariably so high that further carbohydrate seems contra-indicated. Despite this fact we have always given a certain amount of carbohydrate in all such cases, with, of course, a minimum of fat.

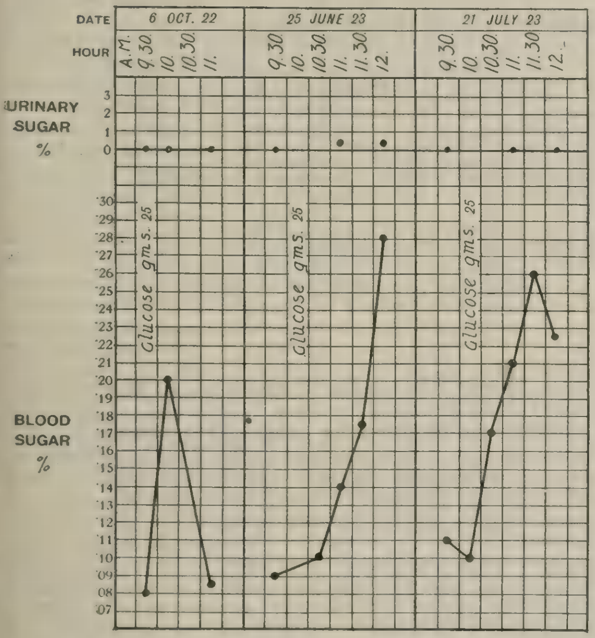
(2) Three cases were so emaciated as to make immediate feeding necessary. In these cases the patient was placed at once upon a calculated adequate diet with insulin cautiously added until the urine became sugar-free. When necessary cardiac stimulants, digitalis, caffeine, &c., were employed. (Chart 4.) The remaining diabetics (22 in number) all commenced treatment on the usual dietetic lines, and every

endeavour was made to treat without insulin. The necessity for such a procedure is obvious in hospital cases, and particularly in the earlier days when insulin was expensive and no provision had been made for obtaining it outside. In three patients only were we successful, but it must be remembered in this connexion that the majority of the cases were severe, and many were cases in which we had had little success on previous admissions. In the others the optimum diet was found, and this proving insufficient for the patients' needs, gradual advances were made with the careful administration of insulin. The first method adopted to gauge the dose of insulin was to give a small dose of insulin followed by a "fixed meal," the food value of which was C. 20, P. 18, F. 25. Blood-sugar estimations were made before the meal and at hourly intervals thereafter for four hours, while the urine was obtained two hours and four hours p.c. By this means we hoped to avoid a hypoglycæmic reaction, and also to correlate the blood and urinary sugar findings with a view to dispensing with the blood-sugar analysis. As expected, we found that while sugar remained in the urine blood-sugar estimations could be omitted, but when the urine became sugar-free they were essential.

The "fixed meal" was incorporated in the diet of the patient once or more often in the day as might be necessary. With further experience the "fixed meal" was dropped, and meals of any type containing the bulk of the day's carbohydrate ration were substituted.

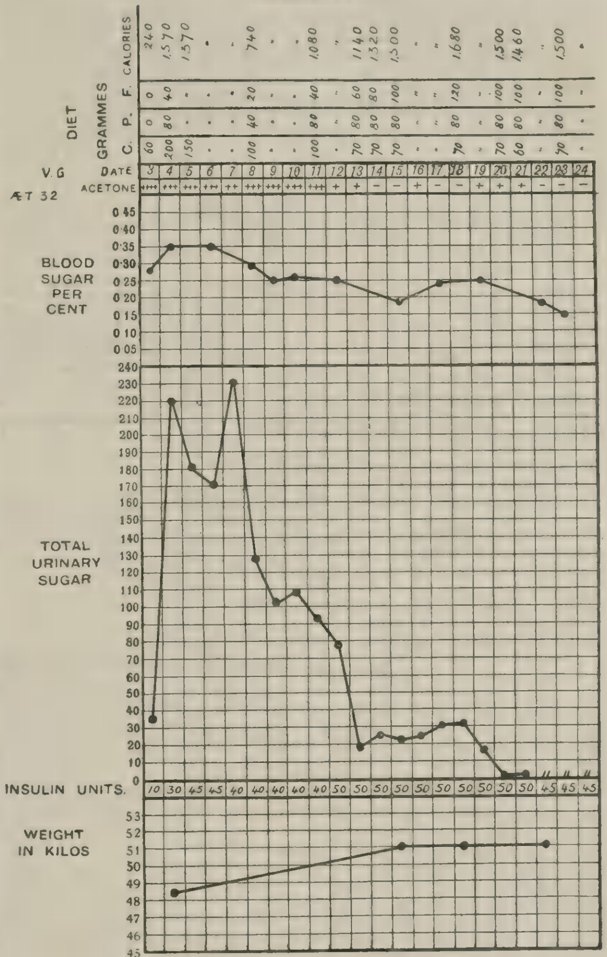
In the earlier cases blood-sugar estimations were made very frequently as explained above. Gradually the number of estimations was reduced until observations were made only in the morning and four hours after each dose of insulin, a method which we still adopt in the earlier stages of all cases while the dosage is being regulated. Later on in treatment a blood-sugar estimation was done in the morning twice a week, and the urine was tested about noon and in the late evening for sugar. In all cases the 24-hour urine was carefully collected and its sugar content measured. Any discrepancy between this result and the noon and evening results was noted, and the necessary adjustments—e.g., increase in the size or number of doses of insulin, or transference of carbohydrate from one meal to another—were made accordingly.

CHART 2.



Speaking generally, treatment followed two lines. The first was that advocated especially by Graham in which the blood-sugar was kept within normal limits with a minimum of insulin and of carbohydrate. Particular attention was paid to a normal pre-breakfast blood-sugar. Undoubtedly this was a most satisfactory method of treatment, and an endeavour was made to treat the early cases, and the young, on these lines. As the blood and urinary sugars are more readily controlled in such cases the majority could be so treated. This method, however, demanded a rather long residence in hospital, while the diets on dismissal were generally inadequate for the more or less heavy work which these patients had to perform. Thus, in the majority of cases the régime was soon broken.

CHART 3.

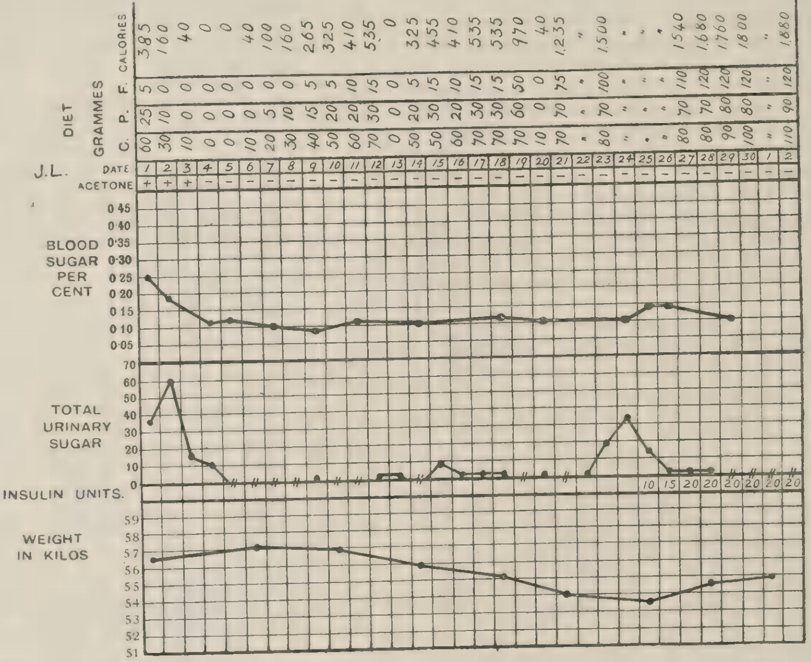


To illustrate the treatment of an "acid" case with insulin. Carbohydrate is given in amount with a minimum of fat, accompanied by large doses of insulin. With the disappearance of acetone from the urine the carbohydrate is cut down, the fat is increased, and insulin dosage is maintained until the urine becomes sugar-free. Subsequently the dose of insulin is gradually reduced.

The second method was to select a calculated adequate diet for the patient, commence with this as soon as it was decided that insulin was necessary, and, by gradually increasing doses of insulin, bring the urine sugar-free with, if possible, a blood-sugar constantly within normal limits. For the old-standing case and for the elderly this was the method of choice; and for the average hospital case, whose carbohydrate tolerance was found to be low and diet inadequate, we considered it to be the more satisfactory.

Insulin was usefully employed to expedite treatment in certain cases. A stout young woman of 22 was admitted with much sugar and acetone in the urine. She would probably have done quite well on diet alone, but as it was difficult to bring the urine sugar-free by starvation, and as time was a consideration, small doses of insulin were administered and continued for a week. Sugar and acetone quickly disappeared, and the subsequent treatment proceeded on the usual dietetic lines. Recently this procedure has been employed more often. It should be used only where, as in hospital, the patient is under careful observation and progress can be checked by blood-sugar estimations.

Chart 4.



To illustrate the treatment of a case of moderately severe diabetes with insulin. The urine is readily rendered sugar-free by starvation treatment; but the tolerance is rather low, and the diet, after three weeks' treatment, is inadequate. An attempt to increase the diet is followed by glycosuria. Insulin is now administered in small doses when the urine is kept sugar-free on an increasing diet.

Hypoglycæmia.

We did not, as has been advocated, cause in each patient a slight hypoglycæmic reaction. In only two cases did such a condition arise. Both patients wakened up in the middle of the night restless and perspiring freely. A cup of hot tea with about 15 g. of bread was sufficient in both cases to clear up the condition in a few minutes. Where it seemed possible that trouble might arise in the night after an evening injection, the patient has been advised to keep a small portion of his carbohydrate ration and to eat it just before going to bed. This has proved very satisfactory, and would appear to be a perfectly sound and safe procedure.

Deaths.

Four cases died during the year, one male and three female.

The man was known to have had diabetes for two years, and on a previous occasion coma had seemed imminent but had been averted. He had been in bed for two weeks before admission, and had become very ill the previous day. On admission he was collapsed and cold. The pulse was rapid and poor in quality. The respirations were frequent and sighing in character. The breath smelt strongly of acetone, and he was very drowsy. The blood-sugar was 0·265 per cent.: the urine contained 5 per cent. sugar, acetone + + +, and a heavy cloud of albumin. There was a marked lipæmia. Under stimulation and with insulin, 45 units, the pulse improved, he became more intelligent, and the drowsiness practically disappeared; but the pulse gradually failed, and he died 12 hours after admission from cardiac failure.

One woman, who had previously been treated in hospital and who was carrying on with insulin outside, was admitted with broncho-pneumonia. The urine contained 2·7 per cent. sugar, and acetone + + +. The blood-sugar was 0·40 per cent. There was no suggestion of drowsiness, and the respirations were rapid and shallow. Under insulin, 90 units, the acetonuria practically disappeared in 48 hours, but she died of cardiac failure, mentally clear to the end.

The second female was a girl who suffered from diabetes of a moderately severe type, together with an extensive tuberculous lesion of the right lung. Treatment of the diabetes with insulin was very satisfactory, but she had several severe attacks of hæmoptysis while in hospital. On dismissal she was transferred to a sanatorium, where she died shortly afterwards.

The third case was somewhat similar to the first. She was a woman of 33 years, admitted unconscious, cold, collapsed, and pulseless. She had a broncho-pneumonia. The breath smelt slightly of acetone, but acetonuria was slight and the tinct. ferri perchlor. test was negative. The blood-sugar was 0·50 per cent. and the urinary sugar 2 per cent. She rallied somewhat under stimulation, but she never became conscious. 60 units of insulin in all were administered, but death occurred within 24 hours.

Review of Results.

When we review the results obtained in these cases it is convenient to consider them under two groupings: (1) Those admitted for the first time during the year, and (2) those who had previously been under treatment. The first group consists of 21 cases, 7 female and 14 male; the second of 12 cases, 5 female and 7 male. The cases in the first group varied in the severity of their condition, but on the whole the majority were of a severe type. Those in the second group were all severe diabetics and patients who had shown but little or no response to "Allen" treatment. Four patients died. The remaining 29 without exception showed improvement under insulin. Thirst and polyuria disappeared with varying rapidity in all cases, and in all the mental outlook was very greatly improved. Pruritus was rarely troublesome. One case of toxic amblyopia benefited very greatly while on insulin. In two cases the knee-jerks, absent on admission, returned after a period of treatment. The results were most striking in the Group 2 cases. All of these cases, 12 in number, showed glycosuria when readmitted to hospital, and several were very acid. All had suffered more or less severe relapses, and seven had been in hospital on one or two occasions on account of these before being readmitted for insulin treatment. Regular work of the type which they could perform was impossible to them. With insulin relapses have been infrequent and slight in degree, and hospital treatment has not again been necessary in any one of them. The appearance of general well-being in patients who had so long borne the dejected air of the chronic and hopeless invalid was very remarkable. The factors which contributed to this will be considered in greater detail.

Weight.

The weights in both groups varied as follows :—

	Gain.	Loss.	Unchanged.
Male	6	7	8
Female	2	4	6

From these figures it is clear that in the majority of cases the weight either remained unchanged or fell *while under treatment in hospital.* The significance of this point is recognised when it is remembered that the great majority commenced treatment on starvation diets. The greatest loss of weight was 4 kilos, and the average loss 1·9 kilos. The greatest gain was 10 kilos occurring in an emaciated patient admitted with a carbuncle on the shoulder. The average gain was 3·9 kilos. A gain in weight was more frequent among the younger patients. In six patients below the age of 20 a gain in weight was recorded in five. The sixth suffered from pulmonary tuberculosis.

Of the 12 patients who had been under treatment once or more often in hospital a gain in weight occurred in six: four remained unchanged and two showed a slight loss amounting in each case to about one kilo. A "follow up" of these cases, however, has revealed a much more satisfactory result. In all who have carried out treatment conscientiously a gain in weight has been invariable. Two women, one a clerkess, the other a mill-worker, have gained 5·5 kilos and 8 kilos respectively in the three months following dismissal. A boy, who gained 5 kilos while in hospital, has gained an additional 9 kilos in six months. Inevitably the less intelligent manual workers have fared most badly.

Carbohydrate Tolerance.

	Gain.	Loss.	Unchanged.
Male	5	1	1
Female	5	—	—

The gain in carbohydrate tolerance among the second group of patients was very constant. One case gained 105 g.; the average gain was 42 g. The "unchanged" case was one complicated by a carbuncle. The "loss" case showed a decrease of 20 g. in tolerance with reasonable dosage of insulin. He was a ploughman who had paid no attention to diet following his previous admission, and who had considerably deteriorated in consequence. Only very occasionally has an attempt been made to increase the carbohydrate tolerance after dismissal. Where improvement has occurred the insulin has been reduced either in amount or in the number of doses required, almost every patient regarding this as the greater boon.

In July, 1923, I reported a case in which under insulin the carbohydrate tolerance was considerably increased, and where subsequently the insulin was gradually cut out, the patient remaining free from glycosuria on the increased carbohydrate. This case was readmitted four months later with a carbuncle, the urine loaded with sugar, and acetonuria + + + +. On this occasion he left hospital with the carbohydrate value unchanged from the previous dismissal, but he now required 35 units of insulin per day to keep the urine sugar-free.

In another case, a man aged 34, treated by diet alone, the carbohydrate tolerance reached 90 g. per day, at which level it ran for eight months. The urine was sugar-free during all this time, and the weight remained stationary. In March, 1924, he contracted influenza, and was ill for about three weeks. Sugar returned in amount, and now he requires 16 units of insulin per day to keep the urine sugar-free on 70 g. carbohydrate.

In none of this series in the brief period under review have we succeeded in raising the carbohydrate tolerance to a level which could be maintained without insulin, even among the early or younger patients.

Acidosis.

This has given rise to little or no trouble. In hospital the urine became acetone-free very readily. In one case acetonuria presisted for 18 days, but this was quite exceptional. Occasionally patients returning to report showed considerable acidosis, but errors in insulin dosage or in diet were always found to account for this condition.

Dosage.

The dose of insulin varied very greatly. Apart from those cases who died, the highest dosage given in any case was 70 units in the 24 hours. The average maximum dose was 30 units. The average dismissal dose was 22 units, the amounts varying from 50 units in one case to 5 units. In all cases where insulin was required on dimissal, diet was so arranged as to allow of at most a morning and evening injection. The objections to a midday dose in the case of working men are obvious. We have even found it more expedient to allow a slight glycosuria rather than to insist upon a more frequent dosage. Hospital patients tend to lose heart and to abandon treatment in despair when too many injections are demanded of them.

Sepsis.

Three patients were admitted suffering from septic infections—one from an otorrhœa, one from a large carbuncle on the shoulder, and a third from numerous carbuncles and abscesses on the back.

In the first case the otorrhœa, which had been troublesome for some time and had suddenly flared up, rapidly cleared up and hearing was much improved. This patient had previously left hospital on 100 g. carbohydrate with 30 units of insulin. While discharge persisted from the ears the carbohydrate tolerance was lowered to 80 g. with the same dose of insulin, but later it returned to its former level. In striking contrast to this result was the experience of the same patient before treatment with insulin was available. He was admitted in November, 1922, with a severe sepsis of the left hand, the result of striking his thumb with a hammer while at work. With difficulty the hand was saved, and two months later healing was not complete. During this time the glycosuria could not be controlled by diet, and his general condition greatly deteriorated.

The second case was very ill on admission and very acid. The carbuncle had been opened just before he came under observation. With insulin the acidosis disappeared, the slough rapidly separated, and healing proceeded comparatively quickly. The effect on carbohydate tolerance and weight in this case has been referred to above.

The third case was that of a very stout man—he weighed 102 kilos—admitted with a large carbuncle on the neck and two others on the back, together with numerous small boils. He was very ill. The urine contained acetone + + + and sugar 5 per cent. Upon a low diet (C. 80, P. 60, F. 20) and with a maximum insulin dosage of 50 units the acidosis and glycosuria gradually disappeared. He passed successfully through three operations under insulin, and healing, though slow, was satisfactory.

Capacity for Work.

Most patients have been able to return to their old employment. One man continues to work as a bricklayer and loses no more time than his fellows. Another works all night in a printing office. Two carry on successfully as commercial travellers. One is at work as a tramway conductor. Two boys attend school regularly. The majority of the women are at home, and these are quite fit for their housework. Two find no difficulty in accomplishing their work as clerkesses; one is a mill-girl, two are in domestic service, and two are nursing, both in rather strenuous employment. Nevertheless, it is difficult to assess the capacity for work in all at the present time. Some who are fitted for light work only are compelled to do labouring or some equally unsuitable work. In time they are forced to give up and remain idle.

ROYAL WEST SUSSEX HOSPITAL.—The ninety-eighth annual report of this institution for the year which ended on Dec. 31st, 1924, shows that the total number of in-patients treated during the year was 1041, while 2423 out-patients made 6715 attendances. Besides these there were 1024 attendances in the X ray department and 1920 patients were treated with electrical massage. Unfortunately, the expenditure exceeded the income by £1624, but there was a gratifying increase in patients' donations—namely, £1649 as against £1415 in 1923.

THE OPERATIVE TREATMENT OF CLEFT-PALATE.*

A RECORD OF RESULTS IN 125 CONSECUTIVE CASES.

BY H. H. RAYNER, M.B., B.CH. MANCH.,
F.R.C.S. ENG.,
CONSULTING SURGEON, MANCHESTER CHILDREN'S HOSPITAL; SENIOR ASSISTANT SURGEON, MANCHESTER ROYAL INFIRMARY.

THE operation for the closure of a cleft-palate is on a plane very different from that occupied by most of the commonly performed surgical operations in that the results, immediate and remote, are uncertain and sometimes very disappointing. It seems desirable, then, that surgeons who have had the opportunity to perform this operation in a comparatively large number of cases should follow up their results, assess these as accurately as they can, and publish them. If we are to make an advance in cleft-palate surgery towards a higher standard of efficiency we can only do so by a study of our present results in relation to surgical technique, type of cleft, and other factors.

After-Results.

The 125 patients in this series have been operated upon by me since June, 1911, and the immediate result—the result at time of discharge from hospital or nursing home—recorded in each case on the list which I kept, so uncertainty from ambiguous statements, or from lack of any statement at all (as is encountered not infrequently when one searches hospital notes), has been avoided.

In regard to the more important matter of the late or functional result an attempt has been made to trace and examine every case in which an immediate or anatomical success was secured; I excluded from these the very young patients (10) on whom the operation has been performed within the last two years on the ground that sufficient time had not elapsed to permit of a proper examination of their speech. Eighty-four patients have been written to, and of these 58 have been traced; 49 of these 58 have been personally examined by me, while in 8 cases I have had to rely on information obtained from the parents or school teacher. One child died two years after a successful closure. It is disappointing that so many (26) have not been traced, but it is not surprising, for many of the operations were done 10 to 13 years ago.

The patients (23) in whom partial union only was secured have not been systematically followed out; most of these present defects of various sizes in the hard palate with an intact soft palate; it is known that some of the older ones have had their speech materially improved by the fitting of an obturator to the hard palate defect. A minority present an intact hard palate with a cleft, complete or partial, of the soft palate; probably many of these could be benefited by further operative measures.

The patients (7) in whom the operation was a total failure must be regarded not merely as failures, but as being in a worse plight than the patient whose cleft has never been operated upon. The same view, it should be added, must be taken of two of the partial union cases in whom the resulting defect was a very wide one.

Type of Operation and Age of Patient.

The Langenbeck operation has been employed throughout, and in this the technique and modifications introduced and described by J. Berry [1] have been followed fairly closely. The operation has not been done in children under 2 years of age, except in the case of unusually well-developed children and those whose cleft involved only the soft palate.

During the past 20 years much attention has been focused on the question of the best age for the operation, particularly so since the introduction of Lane's operation. Probably nearly all surgeons now agree that the whole aim of the operation is to restore the palate as an organ of speech whilst interfering as little as possible with the conformation of the upper jaw and teeth; and that the technique of the operation and the determination of the most suitable age for it must be based on this object and not on the mere cobbling up of a structural defect. Berry and R. W. Murray [2] made this point so clear at the time of the cleft-palate controversy in 1911 that it may seem platitudinous to repeat it now, but one still not uncommonly encounters a feeling in the profession that the operation should be done "early" for the sake of the child's nutrition. As a matter of fact, it is remarkable that so very few infants with complete cleft-palate perish between the performance of the hare-lip operation at 3 months of age, and the time for the palate operation at, say, 2 or 3 years of age. It is often said that the best time for the Langenbeck operation is before "faulty habits of articulation have been acquired," but against this apparently sound advice it must be stated that very good speech results may be obtained by performing the operation long after the acquisition of faulty habits of speech by the child, and also that faulty habits will follow inevitably on a defective operation performed before the child begins to speak at all. The most suitable age, I believe, for the operation is that between 2 and 4 years. The exact age must be decided in each case according to the type of cleft and the condition of the child.

One step in the performance of the operation is worth dwelling on, because I believe it has a most important influence on the quality of the functional result, and that is the stage at which the operator has freed the nasal surface of the soft palate from the posterior edge of the hard palate; at this point he draws down the palatal flap towards himself in order to gauge its mobility, and in doing so he obtains (with good illumination) a clear view of one or two folds of mucous membrane running from the nasal surface of the soft palate upwards along the lateral wall of the naso-pharynx; division of these folds—which contain a considerable proportion of the elevator muscles of the soft palate—will much improve the mobilisation of the palatal flap and therefore render median suture very easy, but such a step should not be carried out except in those cases where the cleft is unusually wide, and then the division should be made sparingly and at one point only. I believe that the poor speech met with in some of my cases has been caused by free division of these folds; such cases when seen a few years after operation may present a palate of very good appearance but with poor mobility.

Causes of Failure to Secure Complete Union.

The causes of failure to secure complete union in this series may be classified as follows:—

1. Performance of the operation in unsuitable subjects—i.e., children of poor physique, anæmic children, and children showing a fairly severe grade of catarrh of the naso-pharynx with muco-purulent secretion.

(2) Infection from pre-existing infection of naso-pharynx, as in No. 1. Latent infection—scarlet fever and measles—at time of operation. A severe infection is likely to cause a breakdown of the entire suture line.

(3) Ischæmia of the edges of the cleft, from too extensive lateral incisions or from the tying of sutures too tightly, is often responsible for a hole at the back of the hard palate. Such a hole, even if fairly large, may close spontaneously in the course of months, but the resulting palate is shortened from dragging forwards of the soft palate by cicatrisation.

(4) Inversion of epithelial edges is another cause of holes, particularly in the hard palate.

(5) Tension. This is usually regarded as the source of all evil, but I have not found it by itself to be a

---

[2] THE LANCET, 1911, ii., 1466.

common cause of failure. In many cases there is little or no tension on the flaps at the conclusion of the operation. Tension begins to exert an influence a few days after operation as the lateral incisions begin to contract, and may then produce a gap in the suture line, particularly at the front part of the soft palate, unless the edges of the cleft have been accurately sutured with a durable material (silkworm gut).

Analysis of Results.

The results obtained in this series are set out in two groups. The first group represents the immediate anatomical results, and the second group the late results as judged by the quality of the speech. It is noteworthy that the series is made up of consecutive cases, and presents an unusually large proportion of complete clefts.

Number of patients operated upon, 125. Mortality = 1, or 0·7 per cent. (death due to reactionary hæmorrhage 24 hours after operation).

A.—*Immediate Results.*

1. Complete clefts, 67. Complete union, 42 (62 per cent.) (three of these after two operations); partial union, 21 (31 per cent.); total failure, 4 (7 per cent.).

2. Incomplete clefts, 57. Complete union, 52 (91 per cent.); partial union, 2 (3 per cent.); total failure, 3 (6 per cent.).

3. Summary of all clefts, 124. Complete union, 94 (76 per cent.); partial union, 23 (18 per cent.); total failure, 7 (5 per cent.).

B.—*Speech Results.*

In regard to the classification adopted in the following tables children classed as "good" have been able to speak clearly in conversation or in dictation, without gross defect, so as to be readily understood by a stranger. Many of them could be fairly described as having normal speech. In the "moderate" class the children have been able to sound the explosive consonants, and "Z" and "sh" when tested by simple words, but their ordinary conversational speech has been definitely defective. In the "poor" class the speech has retained the cleft-palate characteristics, though the child has been able to pronounce some of the explosives with effort; most of these children speak better than the average child with an unclosed cleft. Very few of these children have had skilled training in speech after the operation; probably several in the moderate and poor classes could be materially improved by such means. The numeral before the patient's initials indicates the age in years of the patient at operation, and that after the initials the number of years intervening between operation and examination of speech.

Causal Factors of Bad Speech After Closure.

Examination of these children has shown very clearly that a child who speaks badly a few years after the closure of a cleft palate will be found to have a palate shortened in length from front to back or a soft palate that is not elevated during phonation. A well-formed alveolar arch is also an important factor in the determination of really normal speech as distinct from good speech, and hence a larger proportion of normal speakers will be found amongst the children whose clefts have been incomplete—in these the intact alveolar arch has prevented approximation of the maxillæ.

It has recently been urged by Gillies,[3] Kelsey Fry,[4] and others that closure of a complete cleft in young children (less than 6 years of age) will lead to narrowing of the alveolar arch and also to shortening of the palate, and that our methods of treatment should be radically altered to overcome these defects. This contention has some force and undoubtedly requires careful consideration, but it must be pointed out that marked contraction of the alveolar arch may be seen not uncommonly in cases of complete cleft-palate that have never been operated upon. This is especially the case in children who have had a wide alveolar gap under the hare-lip.

Narrowing of the alveolar arch met with after operative closure of a complete cleft-palate should not, therefore, be ascribed entirely to the operation; operation undoubtedly plays a part important or otherwise according to the age of the child at the time of the operation. Children whose hard palates have been closed during the first or second years of life will show contraction of the dental arch as the result of the operation; but if the operation is performed during the third or fourth years very little narrowing of the arch will result from it.

In regard to the shortening of the palate (a most important factor as a cause of bad speech after closure) I have noted repeatedly in the children in this series that many of the palates were abnormally short before operation, particularly in the case of the incomplete variety of cleft which reaches into the forepart of the hard palate and attains its greatest width anteriorly; in such a type operation will by reason of the width of the cleft shorten the palate still more. Latterly I have been so impressed with the developmental shortening when met with in this type of cleft that I have advised against operation. It is said that median suture of the cleft must, by producing traction from side to side, inevitably lead to shortening in the opposite (antero-posterior) direction. This statement takes no account of the displacement inwards of the palatal flaps after proper mobilisation, nor of the real and immediate increase in length of the palate which the operation produces; this lengthening is due to the reduction of the antero-posterior arch of the palate—often abnormally high in these cases—which follows the falling downwards of the palate as a whole after free detachment of the muco-periosteal flaps and soft palate from the bony palate. Shortening of the palate caused by operation is usually due to the occurrence of a hole at the back of the hard palate; such a hole heals by the gradual pulling in of its edges, and so the soft palate is drawn forwards.

Conclusions.

In conclusion, the proportion of good results outlined in this paper cannot be regarded as satisfactory, yet it is large enough to lead one to believe that a much greater measure of success might be secured by closer attention to the various factors that influence the issue of the operation. The operation is not one to be undertaken by a surgeon whose sphere of practice does not afford frequent opportunities for experience in this field, nor by one whose interest does not extend beyond the immediate result; but undertaken with a proper appreciation of its purpose, technique, and limitations, the operation, I believe, will hold a high position amongst the operations of surgery.

CLEFT-PALATE:

SOME PITFALLS IN OPERATION.

By O. L. ADDISON, F.R.C.S. Eng.,
SURGEON TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND STREET, W.

Although individual surgeons of large experience obtain wonderful results by widely different types of operation for cleft-palate, yet it is common knowledge that the path of the average surgeon is strewn with gaping failures. These failures are in the main due to tension and sepsis.

Median Suture and Flap Operations.

The types of operation in most general use are the median suture (Langenbeck) and the flap operation (Lane). Of these the Langenbeck is undoubtedly the more popular and generally satisfactory from all points of view. Median suture ensures complete closure of the cleft more certainly than does the flap operation; it gives a movable soft palate of better length, and exercises a less harmful effect on the eruption of the teeth and the width of the alveolar arch.

There are few, if any, clefts undamaged by previous operations which cannot be successfully closed by median suture. Moreover, the mortality is negligible, which is far from being the case with the flap method. Its main drawback is that it cannot be used in early infancy, the most suitable age being from 1 to 3 years.

One of the consequences of operation by either method is the dragging forward of the soft palate to a greater or less degree. Recently Mr. Gillies has introduced a method to overcome this. He separates the soft palate from the hard and closes the cleft in the soft palate only, using an obturator to occlude the T-shaped aperture which remains. This no doubt makes for a better closing off of the naso-pharynx and so for better speech. The sufferer from cleft-palate, however, very seldom learns to speak normally, whatever operation has been performed; perfect speech in these cases is almost a curiosity.

A soft palate which is freely movable, and long enough completely to shut off the naso-pharynx, is doubtless an important factor in securing good speech after operation, but by far the most important one is prolonged and careful training in articulation, a desideratum quite unobtainable by the majority of patients. Probably most patients, if given the choice, would prefer an operation which made them independent of an obturator.

In the operation of median suture there are two things which must be avoided at all costs. They are both well recognised, and both are always mentioned in every text-book, article, and lecture on the subject, and both are consistently disregarded by the majority of surgeons when operating. These two things are tension and sepsis. Tension promises failure; tension plus sepsis guarantees it. Over tension we should have complete control, over sepsis control is necessarily less perfect.

Tension.

The relief of tension is usually attempted by means of inadequate lateral incisions. A further handicap to the success of the operation is the customary use of some form of tension suture. The use of tension sutures, to my mind, is a mistake for the following reasons: Ordinary tension sutures will relieve tension for the first three or four days, but at the end of that time, when the main suture-line is at its weakest, they will have so far cut into the palate as to be of little value as supports, while they will form additional foci of infection. The use of lead or other plates no doubt helps to relieve tension, but is apt to cause necrosis, and at best encourages sepsis by the presence of large foreign bodies. It is difficult to imagine a culture-bed of a more encouraging kind for organisms than a tape tied round the hard palate through the lateral incisions as advocated by some American surgeons.

Tension can best be prevented by making long lateral incisions. These should commence on the lower jaw on either side and be carried up the ascending ramus on to the upper jaw to the posterior border of the last tooth. Here the incisions turn inwards, and keeping immediately against the teeth are continued as far forwards as may be necessary, even to the canine tooth. These incisions, if properly placed, are well outside the tensor and levator palati muscles, and they therefore do not interfere with the mobility of the soft palate.

Sepsis.

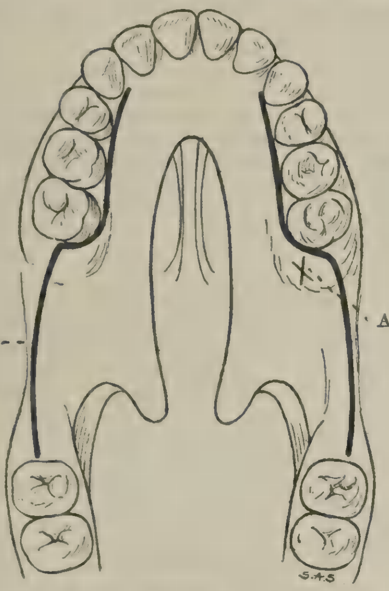
Many children with cleft-palates are very badly nourished, and malnutrition greatly lowers resistance to infection, so that it may be necessary for the patient to be specially fed and nursed into good condition for some weeks before operation. A very great deal more care than is usual should be taken over the preliminary cleansing of the mouth; any mouth is of unknown potentiality as regards its infectivity, and no imaginable precaution should be neglected. Misplaced and carious teeth should be removed, and the gums, if unhealthy, swollen, or spongy, must be made clean and firm. This may be best achieved by wiping the gums two or three times a day with gauze swabs and a weak solution of citric acid. Above all, in every case the tonsils, whether visibly affected or not, must be enucleated, and the adenoids, if present, removed. An exception may occasionally be made in a case of a lesser degree of cleft in a small baby.

I regard the removal of tonsils and adenoids as the most important of all the preliminaries to operation. In the majority of cleft-palate patients, in addition to a large pad of unhealthy-looking adenoids, there are large dirty tonsils with their crypts blocked by collections of cheesy débris. The potentiality of such reservoirs of sepsis for causing an acute flare-up after an operation on the palate needs no emphasis. If the enucleation is skilfully done there is no fear that contraction of the soft palate will take place and make the subsequent closure of the cleft more difficult. The enucleation should be done not less than four weeks before the palate operation. The best age for operation is from 1 to 3 years, according to type of cleft.

Operation.

The child is arranged with a sand-bag under the shoulders, throwing the head well back. The surgeon sits at the head of the table, with his assistant on the child's right and the anæsthetist on the left. As the working space is confined, the simplest *efficient* gag is the best, and this, I think, is Mr. Waugh's small-toothed one. The tongue is held forward by a stitch or small-toothed forceps. Sponging is best done by the surgeon only, the assistant confining his attention to keeping the chin up and the tongue forward with his right hand, while with his left he steadies the patient's head. For the sewing up a good light is absolutely essential, and failing a powerful overhead lamp the best illumination is obtained from a head-lamp worn by the assistant, a much more convenient arrangement than for the surgeon to wear it himself. The mouth being well opened, the operation is begun by making the lateral incision on the side away from the gag.

The incision begins on the lower jaw and is carried up the ascending ramus on to the upper jaw behind the last tooth, then turning inwards it is continued immediately internal to the teeth as far forwards as may be necessary. An elevator is then worked into the incision a little in front of the last premolar, and the muco-periosteum is raised towards the middle line until finally the elevator appears in the cleft. The muco-periosteal flap is then separated from the bone as far back as the junction of the hard and soft palates, and also forward well beyond the end of the cleft, if that is incomplete, and nearly as far as the alveolar border in the case of the complete cleft. During this part of the operation there is free bleeding, which can be controlled by gauze packing. The posterior part of the incision is then dealt with, an elevator being used to widen it and push the whole soft palate and fauces towards the middle line. Special attention is given to freeing the tissues at the posterior end of the alveolar border (see A in diagram). The incision is now plugged with gauze soaked in adrenalin, and after moving the gag across the procedure is repeated on the other side.



L. I., lateral incision. A., alveolar border.

The next step is the separation of the soft from the back of the hard palate. This is best done with a small pair of sharply curved scissors working from the cleft outwards. It is never an easy part of the operation, and in a small baby with a cleft of the soft palate only may be extremely difficult. Nevertheless it must be thoroughly done and the separation carried out as far as the hamular process. It is convenient to work on the side opposite the gag. The two halves of the palate should now be absolutely flaccid, and meet without tension from end to end. The trimming of the edges of the cleft should be left till now to avoid bruising and contamination of the raw surfaces. It is generally unnecessary to cut anything off the edges of the hard palate, but a broad strip of mucous membrane must be removed from the soft. This is best done with a very sharp knife, the palate being made tense by a fine suture passed through each half of the uvula, and held by the assistant; this suture is also a great help in keeping the palate taut during the sewing up.

Suturing is best done with Lane's cleft-palate needles and needle-holder, and the suture material should be the finest ophthalmic silkworm gut. On no account should silk or catgut be used. The suturing starts at the front, the greatest care being taken to see that the edges of the hard palate are well everted and that the stitches are not tied too tightly. The stitches should be about ⅛ in. apart, and should be continued round the uvula for some distance on to the back of the soft palate. At one time I used in addition a continuous suture along the dorsum of the cleft throughout its length as an aid in securing eversion of the edges of the hard palate, but I have given this up as unnecessary. The mouth is now carefully cleaned of dried blood, &c., by small gauze mops wrung out in saline, the suture line is painted with Whitehead's varnish, and the gauze removed from the lateral incisions, though if there is any oozing from them small gauze plugs without adrenalin may be left in, but must be removed within 12 hours.

In a complete single cleft no attempt is made to join the alveolar margin, and in double cleft there is a space left behind the premaxilla. In neither case is it a matter of importance from the point of view of speech or swallowing; for the space rapidly closes in, and in any case patients with complete clefts generally have to wear a small plate on account of the irregularity of the incisor teeth.

This method of operating most usually results in complete union with a good movable soft palate. A failure from an acute flare up of sepsis occasionally occurs and at present appears to be unavoidable; it is common to all types of cleft-palate operations.

Summary.

Best age from 1 to 3 years, depending on type of cleft. Careful attention to the preliminary cleansing of the mouth. Removal of tonsils and adenoids in every case; not less than four weeks before operation. Perfect flaccidity of the two halves of the palate, secured by long lateral incisions commenced on the lower jaw and carried up outside the soft palate and as far forwards as necessary. Meticulous care in sewing with fine silkworm gut which is non-absorbent and is not absorbed. No tension sutures.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ORTHOPÆDICS.

Non-Tuberculous Coxitis.

A meeting of this Section was held on April 7th under the presidency of Mr. H. A. T. Fairbank.

Mr. Alan Todd opened a discussion on the Differential Diagnosis of Non-tuberculous Coxitis in Children and Adolescents. He said that not long ago practically all painful affections of the hip-joint in young people were assumed, sometimes on slender evidence, to be tuberculous, and the rule was to treat them on that assumption. Gradually careful observation showed that a number of cases could not have been due to tubercle, as their behaviour did not accord with the course of that disease. A strong confirmation of this view was afforded by a study of skiagrams, and it was evident that there occurred such non-tuberculous conditions as coxa vara, Perthes's disease, and cystic formations in the upper end of the femur. There still remained a large class in which more exact definition and classification were needed. When the London County Council decided to send crippled children to various centres, and a month's quarantining was established, it was found that some of the children who were thought to have tuberculous disease of the hip got well in six weeks. It could of course be argued in regard to those cases that the diseased condition had been merely patched up, and that there was a liability for the disease to break out again, with disastrous results. The late Prof. Howard Marsh pointed out the importance of activating cases of suspected tuberculous disease, and of refraining from splinting them, for splinting would cause the symptoms to abate, and the patients might be sent away untreated until a serious relapse occurred later; whereas if the children were allowed to run about for 10 or 14 days the diagnosis would become obvious without risk having been run. A number of cases watched for long periods were found to have got well and to have remained well, indicating that they had never been tuberculous. Some 10 per cent. of the cases sent by doctors as possibly early tuberculosis were non-tuberculous, while in private practice, owing to symptoms being noted earlier and their significance being more realised, the percentage was higher.

Classification of Cases.

Mr. Todd's object was to direct special attention to the non-tuberculous cases, so that a comparison of studies and experiences might lead to a more extensive and exact knowledge concerning them. He said non-tuberculous coxitis in children and adolescents was divisible into five categories: (1) traumatic; (2) coxa vara; (3) infected cases; (4) Perthes's disease; (5) miscellaneous. In the traumatic transient coxitis the child had probably had a fall a few days previously, and complained of pain on movement and limitation of movement in various directions. Some got well spontaneously. Some of these patients complained, in addition, of a dull aching pain, and there might be very acute pain at a particular stage of one movement. When that was so, he thought a patch of articular cartilage had been bruised and acutely inflamed. Cases of acute traumatic chondritis got well after a few days' rest in bed with splintage. In some there was a recurrence of symptoms after a few days of running about, and after a time some wasting was noted. He had not seen a case of tuberculosis of the hip which became obvious within six weeks of a local injury, or as the result of a severe blow on the hip. Usually the injury which precipitated tuberculous manifestation was a slight, not a severe one. In juxta-epiphyseal strain the upper epiphysis was rarely separated, and this was demonstrable by skiagram. If there was suspicion that this region had been strained, the case should be kept under observation and X rayed periodically for some months afterwards, as coxa vara might develop. Group (2), coxa vara, could always be distinguished from tuberculous disease by X rays. In an early stage of coxa vara adduction alone was limited, whereas in tuberculosis there was limitation in more than one direction. Some of the cases in group (3) directly followed various febrile conditions, such as pneumococcal lesions, measles, scarlet fever, typhoid, influenza and, in children, gonorrhœal vulvo-vaginitis. Others followed surgical conditions, such as tonsillitis, otitis media, operations on tonsils and on appendicular abscesses. Some of the hip conditions here were probably microbic, but a number were merely toxic apart from micro-organisms. Scarlet fever rarely caused coxitis, but when it did the degree was severe, and there might be ankylosis, either with or without suppuration. Measles was followed by coxitis fairly often, and the arthritis owning this cause was fairly mild. If these cases were splinted, the arthritis usually subsided in two months. Broca had mentioned that in some cases of coxitis, not necessarily microbic, there was a marked flattening of the femoral head. Whether the pneumococcal cases were primary or secondary, as both were blood-borne infections, he did not think the differentiation was material. Thirty per cent. of these cases occurred in children under 14 years of age; they had acute pain, but swelling was slight. There were high fever, delirium, and even mania. The teeth, throat, conjunctivæ, and middle ear were some of the most important foci of infection in this condition.

In coxitis secondary to acute or subacute epiphysitis the onset was sudden and the course rapid; there were marked hyperpyrexia and prostration, and in a few days the X rays revealed gross changes in the joint. This and the marked leucocytosis demarcated it from tuberculosis. Coxitis in an infant under a year old was more likely to be non-tuberculous than tuberculous. In Still's disease and in Perthes's disease the diagnostician had a definite cycle of changes to guide him. Among the miscellaneous cases Mr. Todd gave some attention to hæmophilia, which led to recurrent attacks of pain and limitation of movement. A few weeks in bed usually caused these to subside, and confirmation of the diagnosis arose from X ray examination and the effect of special treatment. A pseudo-coxitis occurred in children who suffered from dyspeptic troubles, including constipation, their pain being definitely referred to the hip-joint. But there was no muscular wasting in these cases, nor definite limitation of movement. Careful dieting and giving a non-protein diet brought about a rapid cure.

In regard to the general differentiation of tuberculous from non-tuberculous cases, Mr. Todd stressed the need for a careful study of the patient's normal temperature variations, and the changes induced by specified amounts of exercise. After the latter the ordinary child would not show any change, but the tuberculous patient would have a rise of temperature half an hour after the exertion. Sir William Hale-White long ago pointed out that in tuberculous cases, at a very early stage, the pulse-rate was accelerated out of proportion to the temperature rise, and the speaker confirmed that; he had not found this in any other conditions. He thought it would be valuable to discuss this topic again in about two years' time, when accumulated experiences on the lines mentioned might lead to the subject being placed on a more firm basis.

Need for Accuracy in Diagnosis.

Mr. R. C. **Elmslie** said he had seen quite recently cases of obvious coxa vara diagnosed, and treated for two years, as tuberculous hip. There was need not only for a greater accuracy of diagnosis in these joint conditions, but also for a more general and thorough dissemination in the profession of the knowledge already acquired. The differentiation of coxa vara from tuberculous hip was first made, without the aid of X rays, on clinical data, in 1881. In a large series of cases of coxa plana, not one suppurated, whereas 70 per cent. of tuberculous cases ended in external suppuration. Radiographic appearances in tuberculous disease of the hip varied so greatly that probably no one had a clear picture in his mind as to what appearances to expect in that disease. Even when cases cleared up there might be reason to suspect they might still be tuberculous. One supposedly tuberculous case he found had simply a cyst in the neck of the femur. Mr. Elmslie said the only way in which progress in this matter could be ensured was by a careful collection of clinical and radiographic observations of both tuberculous cases and other conditions which simulated them. He thought tubercle was such a frequent sequel to measles because the latter disease so lowered the general bodily resistance. He referred to the reports made occasionally of supposed success of a particular treatment in tuberculous cases, when there was grave doubt whether the cases were ever tuberculous. He hoped Mr. Todd would write descriptions of the various types of cases he had encountered, as a guide to others faced with difficult conditions.

Mr. A. **Rocyn-Jones** narrated some cases of difficulty which he had encountered, one being that of a child who had broncho-pneumonia, and soon after this cleared up both hips became swollen. When he saw the child some months later there was a scar over each hip, and the radiographic appearances were like those of tubercle; but it was shown not to be tuberculous. He thought it was very risky to depend on the radiogram; this must be taken with the history and the clinical course. A valuable sign of an early intra-articular lesion was the production of pain on performing rotation of the limb, though abduction and adduction might cause no distress.

The **President** said synovitis of the hip-joint due to trauma was apt to be forgotten. In doubtful cases his practice was to allow the child to walk about for a time, though if it was acute there must be periods of rest. If it was a mild case and not tuberculous, the rule was for the condition to clear up absolutely. Tuberculous synovial disease was very rare; there were two specimens of it at Great Ormond-street Children's Hospital. Both those patients came with subluxated hips, and there were no definite X ray signs apart from the dislocation, no erosion of acetabulum or head, and therefore they were not congenital dislocations. Both died of tuberculous meningitis. He was not familiar with the condition of juxta-epiphyseal strain apart from definite displacement of epiphysis; usually, he thought, there would be detected a small displacement of the head. With regard to endocrine disorders, Mr. Fairbank said a certain number of children with displacement of the head of the femur were slow in development, and sexually they were definitely behind the normal. The infective group of cases were most difficult to diagnose definitely. He blamed the *Staphylococcus aureus* for many of the puzzling and obscure cases. In Still's disease there was often trouble in the articulations of the cervical spine. Hip trouble which was primarily pneumococcal seemed to respond well to opening and washing out.

Mr. Whitchurch Howell said that during his association with an infectious fever hospital of 500 beds he only operated on three cases of arthritis in children, and in those, all under 3 years of age, it followed scarlet fever. One of them re-established complete range of movement, another had subluxation following and was walking with the aid of a calliper splint, while the third was stiff, short of ankylosis. Broca, in his last book, was emphatic that all cases of arthritis following measles were tuberculous.

Dr. Knyvett Gordon, speaking as a pathologist, referred to the value of hæmological examination, not a mere blood count. Tuberculous cases invariably gave a blood picture differing from that of infected cases. In closed tuberculous cases (those having no sinuses) there was a leucopenia, with relative lymphocytosis, while in infective cases there was a polymorphonuclear predominance. There had been a remarkable reduction of cases of suppurative hip disease since mastoid operations were done in fever hospitals. He considered that bacteriological examination only was of little use for diagnosis; it should be followed by inoculation into a susceptible animal. Fluid from a tuberculous joint was usually sterile from an ordinary examination, but it killed a guinea-pig.

WAR SECTION.

A meeting of this Section was held on April 6th, Surgeon Vice-Admiral Joseph Chambers, the President, being in the chair.

Colonel J. Crawford Kennedy opened a discussion on

TUBERCULOSIS IN THE SERVICES.

He dealt with the matter from the statistical side, basing his work on the earlier reviews by Melville and Simpson. There appeared to be no detrimental influence in foreign service, the incidence of tuberculosis among soldiers being approximately the same at home and abroad. Between 1860 and 1906 there had been a very marked improvement, the total loss from tuberculous infection dropping from 9·2 to 2·2 per 1000. The factors underlying this were improved housing and surroundings; to a certain extent a lowering of the age of the army and changes in nomenclature might also have contributed. During those years there had been an improvement in the civil population of 50 per cent., while the improvement in the army was 80 per cent. In 1860 the death-rate was 9 per 1000, in 1914 it was 1·6; in 1921 it had risen slightly to 2, where it had remained steady. While better rationing, better housing and conditions of life, improved medical and general physical supervision, and more careful recruiting might all be mentioned as contributing factors, none of them was sufficient to account for the change, and it was to the reduction of the disease in the civil population that we must look for an explanation of its reduction in the army. Comparing the statistics, it was found that there was a slight balance in favour of the service up to 1914 and in favour of the civil population since 1921. The rejections for tuberculosis from recruiting stations were on the whole increasing, especially since recruiting began to tighten up in 1921 after the rather more lax regulations of the post-war years. It must not be forgotten that the material presenting itself for recruitment in 1920 was that which had suffered from war malnutrition at the most susceptible period of life—viz., 14-16—and was therefore more likely to develop subsequent infection. The wastage from tuberculosis had remained at a steady figure since 1912. The greatest incidence of the disease was seen between the fifth and tenth year of service, the figure being 4·4 per 1000; in later decades the figure was 2 or 3 per 1000, while during the first five years it was only 0·86. The curve for the age incidence rose steadily, reaching its maximum at 40, unlike the curve in civil life. The ratio of liability in the army to that in civil life had been as 1 to 7; it was now as 1 to 4, and thus there appeared to be a process of approximation taking place. In conscript armies on the continent the incidence was much higher.

Surgeon-Commander C. H. Dawe spoke of

Tuberculosis in the Navy.

Between 1891 and 1904 the incidence had been highest at the middle period of life, since then it had become higher in the young adults and much lower in the middle decade, while remaining about the same for the older men. Economic status and hygienic conditions had little effect on the young adult type; the problem of tuberculosis between 10 and 30 years of age was a problem of feeding. In the navy the rate followed that of the civil population. The life at sea was far from being ideal, but the efforts made to overcome the difficulties of diet had resulted in the marked decrease of the tuberculosis incidence in the decade 30–40. Malnutrition had little influence on the development of the disease in the later decades; that was a problem of wear and tear. There had been rather more tuberculosis in the navy in 1919–22 than in 1913; this was probably due to the results of malnutrition during the war period. Something might be done to make the change in environment less sudden and trying for some of the young recruits. The incidence in merchant seamen corresponded to that of naval men up to the age of 30 and then increased steadily with age. This was due to the wear-and-tear factor and the poorer hygienic conditions in the merchant service.

Wing-Commander H. A. Treadgold said that the statistics of

Tuberculosis in the Air Force

were of necessity few, but such as they were they confirmed the findings of the army and navy. There appeared to be no difference in the incidence of the disease in squadrons abroad and in those at home. This was strange, as the total sickness incidence was very much greater among the men on foreign service; they were subjected to much more trying conditions of climate, dust, and absence of fresh foods, and, although there were no figures, the general impression was that the incidence in the civil populations of the occupied regions was very high. The probable explanation was that the men abroad did not come into intimate contact with the infected civil population in the way that men at home did.

A paper by Fleet-Surgeon W. E. Home giving the

Statistics in the Mercantile Marine

was read by the Secretary. In the year 1921–2 only one case of tuberculosis died in a sailing ship; the incidence in steamships was slightly higher, the lascars being more affected than white races. He quoted Sir William Osler's opinion that the tuberculous soldier brought the disease into the service with him.

Surgeon-Commander R. J. Mackeown agreed with this dictum and expressed the opinion that the standard of recruitment should be raised. He asked if recruiting medical officers examined the urine, investigated the history, especially of frequent colds, and cross-examined the patients as they should. It was not uncommon to find men in the services who had previously been in sanatoria. Every case of pleurisy should be looked on as a certain case of future pulmonary tuberculosis and removed. It was useless to send such cases back to the hardships of naval life after patching-up in hospital. He asked whether naval medical officers fully realised the dangers of early tuberculosis occurring in a crowded mess deck. The artificial means of aerating between-decks helped to spread infection if any was present. Something should be done to eliminate dust; the institution of vacuum cleaners would be of advantage.

Wing-Commander A. V. J. RICHARDSON referred to the dangers of dust. He asked whether the cases occurring about 25 were really primary infections or whether they were not due to the lighting up of an old infection.

Surgeon-Commander J. O'HEA said that the recruiting medical officer could hardly do more than examine the chest fully and exclude all cases of abnormality of any sort. The urine was tested in every case and the history investigated as far as possible, but it was difficult to elicit. Men would often say they had had no illnesses and had never been in hospital, and yet would admit that they had undergone a period of sanatorium treatment if that question were specifically put. All men who had had pleurisy or been exposed to a massive infection at home were rejected.

Surgeon Vice-Admiral Sir ROBERT HILL asked which ratings of the navy were most severely attacked by the disease. The limited sleeping accommodation must be accounted one of the chief causes of its spread.

Squadron-Commander J. MACDONALD spoke of the thorough examination carried out on recruits for the Air Force. The history could not be relied on, but any suggestion of tuberculosis was investigated. He asked whether X rays might not help in the assessment of the lung of the recruit.

The PRESIDENT said that every possible precaution was taken in the navy to detect early cases; there was periodical examination of the chests of all men and any doubtful case was sent to hospital for X ray examination. Reports were required as to the name of such cases, place of station, family history, rating; as to employment between decks, with particulars as to the ventilation of the deck concerned, a list of the ships in which the men had served; and information as to the general health of those ships and previous cases reported from them. Vacuum cleaners were being installed, and many other improvements designed to raise the standard of naval hygiene were in view.

Colonel CRAWFORD KENNEDY, in reply, said that careful recruiting had already eliminated the young-adult tuberculosis of the soldier. The cases which appeared between 35 and 40 could not possibly be eliminated by the recruiting medical officer. He did not think X rays would be of much use; the soft type of tuberculosis could not be recognised on the film and the fibrotic type seen there might never break out again. The Americans used X rays a good deal, but insisted that only a stereoscopic view was of any value. That the factor of intimacy with the civil population was one of importance was evidenced by the fact that the incidence was particularly high in the Armies on the Rhine.

Surgeon-Commander DAWE pointed out that 60 per cent. of naval recruits entered between the ages of 14 and 16, when the tuberculosis incidence was very low. The rates for seamen and stokers were identical, that for the marines slightly higher. The ratings varied from year to year in the number of cases reported. An exhaust system of ventilation would probably be more satisfactory than the present supply system.

Reviews and Notices of Books.

ANTHROPOLOGY.

The Origin of Man. By CARVETH READ. Cambridge University Press. 1925. Pp. 100. 5*s.*
Man and His Superstitions. Same author and publishers. Pp. 278. 12*s.* 6*d.*

THESE two books form together a second edition of "The Origin of Man and of His Superstitions," which was originally published in 1920. They have now been separated with some advantage, for in the first those who are chiefly interested in man's physical development may read, at a surprisingly moderate cost, a most interesting account of the ideas of the late professor of philosophy and comparative philology at University College as to how man comes to be so different from the anthropoid apes.

Prof. Read's theory is, briefly, that early, let it be called pre-human, man got a taste for animal food and took to hunting in packs like wolves. In this way his legs developed in comparison with his arms, he left the forest and took to running in the open instead of shuffling about in and under the trees. To hunt successfully needs numbers and organisation, and hence these men came to form considerable communities which were under the control of those who were marked out as leaders by their obvious success in the chase. Emerging from the same stock the ourangs and chimpanzees have made much less progress because they have not faced such difficulties, and from the lower apes, which often live in communities, they have developed into solitary or at most familial groups content with vegetables and more apt at defence than attack. The pack must be clearly distinguished from Mr. Trotter's herd, aggregated for mutual comfort and protection: *Lycopithecus* was like a wolf rather than a deer, which may explain, among many other things, the foul savagery which, as medical men know better than most, is in us all. Prof. Read's exposition is singularly clear and readable, punctuated with many wise and witty remarks, and he puts his case with a persuasive moderation which leaves his thesis among that delectable list of topics which can be discussed for ever and never solved.

In "Man and His Superstitions" the author carries on his account of how the wolf pack grew into a settled human society. So long as the pack hunted, empirical success in getting food indicated who was the leader by considerations which made a convincing appeal to everyone's stomach. But when they grew so skilful in the chase that they had time to think of kennels, so to speak, all the problems of the leisured human life began to arise and not least among them the problem of government. In Prof. Read's view, there were men shrewd enough to make use of the beliefs in magic and animism, which were then appearing on the human horizon, to give them prestige enough to maintain the necessary custom and tradition: the chief huntsman was replaced by the magician, who in turn grew into a wizard-king or a priest-king or a king supported by wizards and priests. Hence the fundamental importance of superstition in the subsequent development of man and hence its prevalence to-day. The author discusses then magic, animism, wizards, omens, totemism, and all the allied vagaries, as they seem to us, of the human mind. It is a very strange tale and makes us wonder whether we are really much more rational than the Australian natives described by Spencer. Prof. Read seems doubtful and of the future he will hazard nothing.

CHRONIC APPENDICITIS.

Les colotyphlites et le syndrome de la fosse iliaque droite. Par le Docteur A. C. GUILLAUME. Paris: G. Doin. 1924. Pp. 386. Fr.35.

MOST surgeons will be agreed as to the extremely unsatisfactory nature of "Chronic Appendicitis" as a diagnosis. It is true that occasionally the removal of a fibrotic appendix produces a remarkable cure, but too often a temporary relief is followed by recurrence of all the former symptoms. Pain in the right iliac fossa is one of the commonest complaints, but Dr. Guillaume is so impressed by its doubtful pathology and the extreme uncertainty of a precise diagnosis that he simply describes the condition as "the syndrome of the right iliac fossa." From this standpoint he discusses the many possible pathological conditions which may be associated with this syndrome, and although he arrives at no very definite conclusion the monograph is of considerable value. It consists for the most part of a critical examination of the literature of the subject, and the thoroughness of his research in this direction may be gauged by his bibliography which extends to over a thousand references. Criticism throughout is trenchant and well founded, and he illustrates his views by numerous examples drawn from his own practice. The book should be of real value to students of intestinal stasis and of chronic abdominal pain.

THE DEGENERATIVE DISEASES.

By LEWELLYS F. BARKER, M.D., Professor Emeritus of Medicine, Johns Hopkins University; and THOMAS P. SPRUNT, M.D., Associate in Clinical Medicine, Johns Hopkins University. London and New York: Harper and Brothers. 1925. Pp. 254. 15*s*.

THE progressive campaign for health which has been one of the most striking achievements of the first quarter of the twentieth century has tended to concentrate its efforts on the communicable diseases and lately upon the ante- and post-natal care of the child. A study of the mortality statistics shows that certain chronic diseases of later life still continue their ravages unchecked. In this recent addition to the public health series edited by Dr. Allan J. McLaughlin, Prof. Barker and Dr. Sprunt show how these degenerative diseases may be added to the field of public health activity. "Obviously," they write, "from their nature, the degenerative diseases of senescence cannot be prevented except by the barbarity of destroying life before this stage has been reached. Indeed, one ideal of preventive medicine might be to prevent all other diseases and to permit all men to die in the fullness of years a 'natural' death from some degenerative condition. The problem of hygiene in regard to this field is to postpone the inauguration of the degenerative change, to retard its progress, to avoid, if practicable, certain expected complications, and to promote as far as possible the comfort of the patient." Such a problem will be solved by intelligent coöperation between the health worker and the community, and the aim of this book is to educate "that highly intelligent group of people made up of physicians, lawyers, clergymen, teachers, social workers, clubwomen, business men, business women, and others who are leaders of thought and opinion."

A popular book on health should be interesting, it should present the facts without prejudice, and persons of ordinary intelligence should be able to grasp the significance of the facts thus put before them. This book fulfils all these conditions. It begins with a section on the general considerations of the causes of these degenerative diseases and the rôle of heredity and environment in their production. The principles of prevention and postponement of these diseases are then set out with reference to eugenic and euthenic factors, and in the latter connexion due stress is laid on both external and "internal" environment. The subdivision of internal environment denotes the influences playing upon the organs and cells of the body arising through the activities of other cells or organs of the same body, and it serves to link up the external influences of air, food, and water, for example, on the one hand and the products of disordered metabolism on the other. The third section, comprising about one-half of the volume, deals with the special degenerative diseases. Portions dealing with auto-intoxication, focal sepsis, alcohol and tobacco, and the endocrine organs are in particular marked by a sane and restrained attitude: the facts are presented with a complete absence of the sweeping dogmatism so common in books of this nature. If the chapters on the special diseases appear a little more technical than one would have expected it must be remembered that the authors have written this book for a particularly intelligent section of the community.

ELECTRO-THERAPEUTICS.

Die Diathermie. Fourth edition. By Dr. JOSEF KOWARSCHIK, Primararzt und Vorstand des Institutes für physikalische Therapie im Kaiser-Jubiläums-Spital der Stadt Wien. Wien und Berlin: Julius Springer. 1924. Pp. 231. M.129.

SINCE the appearance of the preceding edition of Dr. Kowarschik's work on diathermy in 1921 the therapeutic field of diathermy has been considerably widened. The present edition has been enlarged by the addition of 65 pages and 19 illustrations. To the section dealing with the non-surgical uses of diathermy the author has added accounts of his own experience and that of others in the treatment of diseases of tendon sheaths and bursæ, of anterior poliomyelitis and paralysis, of occupation neuroses, of exophthalmic goitre, of vaso-motor disorders, of diseases of women, and of certain affections of the skin; the last named include varicose ulcers, frost-bite, scars and chronic ulceration caused by X rays. The author is convinced of the value of diathermy in the treatment of amenorrhœa and dysmenorrhœa (when there is no organic disease of the pelvic organs) and of chronic inflammation of the uterus and its appendages. The section dealing with surgical diathermy has been enlarged, though scarcely in proportion to the importance of the subject or the space allotted to other branches of the treatment with which the book deals. In the section on electrotechnics are given particulars of diathermy machines which were not described in the previous edition. One of these is a model by an English firm. The principle of the production of sustained high-frequency currents with the aid of the hot cathode valve is described. Dr. Kowarschik's work has thus been brought up to date. It gives a brief though concise account of the subject of diathermy, and the author makes no undue claim for its therapeutic value. The book is well printed and clearly illustrated, and a full bibliography has been added.

PATHOGENIC MICRO-ORGANISMS.

Eighth edition. By WILLIAM HALLOCK PARK, M.D., Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College; ANNA WESSELS WILLIAMS, M.D., Assistant Director of the Bureau of Laboratories of the Department of Health; and CHARLES KRUMWIEDE, M.D., Assistant Director of the Bureau of Laboratories. London: Baillière, Tindall and Cox. 1925. Pp. 811. 30*s*.

THIS text-book, which has long been a standard American work on bacteriology, has been considerably enlarged and to some extent rearranged. The book, however, retains its familiar form and those features which have given it a well-deserved popularity. It is becoming, each year, more and more questionable if it is desirable to include a large section on methods in general text-books, since these are now so thoroughly dealt with in separate publications. In this book some 80 pages, or about a tenth of the volume, are occupied by this subject. It would be a pity altogether to lose this section, as it is ably written, but its separate publication might be worth considering since the size of the volume is steadily increasing. This edition includes a summary of all the recent advances in bacteriology, including the d'Herelle phenomenon, the work of Olitsky and Gates in influenza, and of George and Gladys Dick and others in scarlet fever, as well as Prof. Park's own most recent results in active immunisation against diphtheria. The section upon immunity and the serum reactions still remains one of the best in the book. The general get up and binding are perhaps not quite so pleasing as in earlier editions and some of the blocks are showing signs of wear.

The book still remains one which, being based upon wide experiences, can be safely recommended as authoritative and trustworthy.

The Laboratory Book of Dairy Analysis.

Third edition. By H. Droop Richmond, F.I.C., Chief Analyst to Boots Pure Drug Co., Ltd.; late Analyst to the Aylesbury Dairy Co., Ltd. London: Charles Griffin and Co. 1925. Pp. 118. 5*s.*

This laboratory guide to all the common analytical processes likely to be encountered in routine dairy-work has reached its third edition. We are happy to repeat the statement made in these columns in respect of the last issue—namely, "the book is the best contribution on the subject that has yet appeared in the English language." For a laboratory guide to technique the volume could be held up as an example to other authors about to write a book on similar lines. The descriptions are very brief, and although no word is wasted, the accounts are complete and workable. Logarithm tables, and an account of the "Dairy Scale" are included to simplify calculation. The book is divided into six chapters dealing with introductory matter, the analysis of milk and of its products, and their applications, and of butter and cheese. In an appendix the methods for the preparation of standard solutions have been described.

Medical men responsible for chemical pathological routine work in general hospitals have probably not been regarded as an audience by the author, but workers in this field are often confronted with problems involving milk analysis, and are frequently questioned as to whether a certain dried preparation is made by the roller or by the spray process. The medical chemist has also to analyse human milk, which is quite a different problem from cow's milk. Mr. Richmond might bear these points in mind when he prepares his fourth edition.

Dr. Chavasse's Advice to a Mother.

Nineteenth edition. Revised by G. T. Wrench, M.D., Past Assistant Master, Rotunda Hospital, Dublin. London: J. and A. Churchill. 1925. Pp. 346. 2*s.* 6*d.*

The fact that this well-known little book has reached its nineteenth edition and its 370th thousand is sufficient testimony to its value, proving that it is easily understood and essentially practical. The chapters on the feeding of infants have been rewritten and certain other portions revised in accordance with the recent progress of medical science. Dr. Wrench advises, in his preface, that a mother should familiarise herself with its contents so as to be able to turn to the section she requires in time of need. A good index facilitates this. The new portions are quite in keeping with the modern teaching on infant feeding, and most of the methods recommended have been extensively tried by the reviser.

Biology.

A Text-book of Biology. Fifth edition. By W. M. Smallwood, Ph.D. London: Baillière, Tindall and Cox. 1925. With 249 text figures and 3 plates. Pp. 393. 16*s.*

The author is professor of comparative anatomy in the Liberal Arts College of Syracuse University, New York, and his book is intended "for students in general, medical, and technical courses." The first 113 pages are given to a study of the anatomy and physiology of the frog, the next 49 to unicellular organisms: there follow a few more "types" and then 132 pages on theoretical interpretations, evolution, genetics, adaptation, parasites, and so on. The plan is unconventional and is perhaps a good solution of the difficult problem of devising a satisfactory course in biology for the arts student: it has evidently met with approval. Our criticism of its execution in this particular case is that the treatment is not disciplinary enough: familiarity with all the contents would give a facility to talk about biology in its most modern aspects, but it would guarantee no sound knowledge of its fundamentals. There is too much about Mendelism and death-rates from infectious diseases and too little comparative anatomy. The miraculous X Y Z often seems to be preferred to the majestic A B C in American education. Let it be admitted that the preference has its drawbacks, it also has its virtues.

Biology. By Patrick Geddes and J. Arthur Thomson. London: Williams and Norgate. 1925. Pp. 254. 2*s.* 6*d.*

Everyone will welcome the active resumption of the splendid Home University Library, though it must be confessed that this will hardly rank as one of the best volumes. To write on biology in a small compass is obviously a difficult task, and one asking for a nice selection of the topics which are to be dealt with and the readers who are to be addressed. The authors have devoted their space to a very generalised treatment and have written in such a style that no one without a tolerably good knowledge of zoology and botany will be able to understand all the casual and implicatory references which abound. And technical equipment will not guarantee that readers will always understand what is meant. There is in many parts a vagueness about the argument, sometimes about the individual sentences, which raises a little suspicion that the authors have not defined clearly to themselves what they intend to convey. The chapter, for example, entitled "What is Life?" reads pleasantly enough until one attempts a mental summary. Biology is of course in parts a vague sort of subject, and great mysteries no doubt need mystical treatment. But in parts it is precise enough, and a greater proportion of the commonplace would not have seriously dimmed the prevailing tone of the book, which is a buoyant optimism that the world is a wonderful place and a harmonious whole in which the amœba and town-planning both have their related places. Perhaps, too, the authors have found the difficulty which is a constant obstruction to progressive minds—the fact that the evolution of meanings is always in advance of the evolution of words.

JOURNALS.

Tropical Diseases Bulletin.—The issue for March, 1925, is full of useful information, of which Dr. C. M. Wenyon has supplied the greater portion. He has reviewed the recent literature of relapsing fever and other spirochætoses, rat-bite fever, and infectious jaundice. To kala-azar there are devoted some 49 papers, of which those dealing with the transmission of the disease by the sandfly—*Phlebotomus argentipes*—by R. Knowles, L. E. Napier, and R. O. A. Smith, are the most important, for it would seem that this long-contested problem is on the eve of being solved. Leprosy is adequately treated by Leonard Rogers, and tropical dermatology by W. Jenkins Oliver. There is a review of recent articles on rabies by A. G. McKendrick which will be found opportune.

The monograph entitled General Systematic Bacteriology, by Prof. R. E. Buchanan, reviewed in The Lancet of April 11th, is obtainable in this country from Messrs. Baillière, Tindall and Cox.

AN EMPIRE PRODUCTION

OF GREAT VALUE TO THE INVALID

Burgoyne's Tintara

OBTAINABLE OF ALL WINE DEALERS.

4/- **6/-**

Ferruginous.

THIS PURE AUSTRALIAN WINE was introduced in 1871, it has been highly recommended by the Medical Profession in all cases where strength and nerve force have required building up. In anæmia, debility, neurasthenia and in convalescence after any illness, this full-bodied, generous wine, palatable as well as health producing, has proved itself the finest of all natural stimulants.

Sample Bottle sent free in the United Kingdom, on receipt of professional card.

P. B. BURGOYNE & CO., Ltd.,
Burgoyne House, Dowgate Hill, London.

THE CLAYTON ANILINE Co LTD

ASTHMA & HAY-FEVER

A new and successful method of treatment with

ELBON "CIBA"

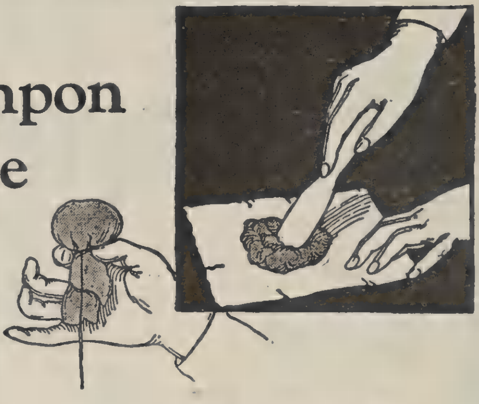
(Cinnamolyl-p-oxyphenylurea)

TABLETS, 7¾ GRAINS.

Full particulars and reports to physicians on request.

Pharmaceutical Department,
68½ UPPER THAMES STREET, LONDON, E.C.4

This Vaginal Tampon liberates Glycerine *gradually*



THE most efficient vaginal tampon is one which, containing a high glycerine content, is so compounded that when it is packed around the cervix, the glycerine can be liberated *gradually*, thus prolonging the beneficial action of depletion.

Antiphlogistine, used as a Vaginal Tampon, not only accomplishes this, but the large c. p. glycerine content of Antiphlogistine, combining with the liquid exudate present, sets up an acceptable degree of heat with consequent ease and relief to the patient.

Use this easy way to make this efficient Tampon

Heat the Antiphlogistine to the required temperature, place a quantity of it in the centre of a square of gauze, as shown in Fig. 1; gather the gauze up around the Antiphlogistine, taking care to leave the ends of the gauze free so that they may act as a drain as shown in Fig. 2. Use a suitable speculum, packing the tampon snugly around the cervix.

"Pregnancy—its signs and complications"

is the title of a 16-page booklet *free* to all Obstetricians and Gynecologists. May we send you one?

It treats of the acknowledged use of Antiphlogistine in Mammary Abscess, Phlegmasia Alba Dolens, Mastitis, Post Partum Metritis, Fissured Nipple, Caked Breast, Vulvalar Edema, Hemorrhoids, Retention of Urine, Obstinate Neuralgia, Sub-Involuted Uterus, Adenitis.

THE LANCET.

LONDON: SATURDAY, APRIL 18, 1925.

IODINE IN EXOPHTHALMIC GOITRE.

The relationships between enlargement of the thyroid, hyper-thyroidism, and the iodine content of the thyroid have given rise to much discussion and to a large volume of experimental and clinical work. As far back as 1820 it was first realised that endemic goitre was often associated with a low iodine content of the gland, and that a great improvement—if, indeed, not a complete cure—could often be achieved by the administration of small doses of iodine. It has long been known that endemic goitre has a geographical distribution, and it is probable that this is due to the fact that there is but little iodine distributed in these areas. This, however, is not the sole factor, and McCarrison[1] has shown that in certain conditions—especially those occurring in the sexual changes in women—the iodine requirements may be much in excess, and thus, although the available quantity of this substance may be up to the normal standard there is insufficient for the immediate needs of the patient. In many infective and other conditions, also, the available quantity of iodine cannot be utilised, and thus the patient again suffers from a deficiency.

The balance of experimental and clinical evidence supports the view so strongly held by the late Prof. Kocher, that the symptoms of exopthalmic goitre are due to hyperthyroidism and that the administration of iodine in considerable doses in cases of simple goitre might change the picture to one of hyperthyroidism. The chemical investigations of de Quervain[2] have shown also that many of the characteristic varieties of exophthalmic goitre are associated with a high iodine content both as regards the percentage and the total amount. For these reasons it has always been considered unsafe to give iodine or iodine-containing preparations in any form of goitre in which there was evidence of hyperthyroidism. It is of interest to note, however, that in certain varieties of exophthalmic goitre de Quervain found that the iodine content of the thyroid gland was low, and often, indeed, lower than that found with colloid goitre. Last year Plummer and Boothby[3] first put forward the view that even with hyperthyroidism there was often an insufficiency of iodine, and F. R. Fraser,[4] working at St. Bartholomew's Hospital, has found that generally the greater the hyperplasia of the gland the lower the iodine content. For these reasons Plummer and Boothby advocated the administration of some simple form of iodine in the treatment of exophthalmic goitre. Six hundred cases were so treated, of which 43 were studied carefully. Iodine was given in the form of Lugol's solution—that is, a 5 per cent. iodine and 10 per cent. potassium iodide, ten drops daily being administered. From the result of their experiences they state that approximately two-thirds of the patients will be greatly benefited, one-quarter slightly benefited, and 1 in 20 not benefited. Mason[5] states that he has had a similar experience with Lugol's solution, but emphasises the fact that the symptoms increase as soon as the treatment is stopped. Starr, Walcott, Segall, and Means[6] also note the temporary character of the improvement and that in some cases no effect was observable. The observations of Fraser led to very similar conclusions. He found that in many cases there was an enormous improvement following the administration of some simple form of iodine. The basal metabolic rate and the pulse both fell considerably and the weight increased; nevertheless the patients were only relieved and not cured. Any mental upset or stress would often reproduce the exaggerated symptoms. If too large a dose were given the symptoms would be increased instead of alleviated, and as soon as the administration was stopped the symptoms would all return. Hyman and Kessel[7] did not agree with these findings and were of the opinion that any improvement which took place was due to the rest and general medical treatment, and that if such treatment were carried out for a period of six weeks and the iodine then administered progress was no more rapid than, if indeed as rapid as, it had been before the administration was commenced.

The article published by Dr. A. S. Jackson in The Lancet of April 11th now records observations carried out on 63 patients with exophthalmic goitre treated at Madison, Wisconsin. In this group of cases which were all subjected to operative treatment, there were no surgical mortalities, neither were there any medical deaths. No patient had been refused operation. The author regards the successful treatment of this group as being attributable to the use of iodine. He found that not only did the patient's condition greatly improve, but the post-operative hyperthyroidism was thereby almost entirely obliterated. Proceeding cautiously at first and giving only ten drops of Lugol's solution daily for a period of three months or longer he found that although there was marked improvement there was no clinical cure. The progress was, however, so satisfactory that preliminary operations such as ligation were reduced in number and thyroidectomy was carried out at the first stage. As time went on the dosage of Lugol's solution was increased until 30 drops a day were given up to 48 hours before operation, when the dose was increased to 40 or even 50 drops. He states that now the patients are frequently allowed to take the Lugol's solution at home and submit to operation on the morning after entering hospital. By post-operative administration the progress was rapidly increased, so that many were up and about on the fourth day and usually were allowed to leave the hospital on the fifth or sixth day, but this did not include cases with decompensated hearts and visceral degeneration. The clinical improvement in the pre-operative course is often remarkable, the rapid and almost choreic movements cease almost at once, and from nervous and anxious patients they pass to a condition of calm and quiet composure. The pulse-rate is noticeably slowed and the patients rapidly gain in strength. He states, however, that other factors are of importance in the great reduction of operative mortality, among which he would class satisfactory team-work and the performance of the operation earlier in the stage of the disease. He lays special stress upon the rapid improvement and upon the fact that none of these patients were hospitalised for an average of more than five days.

[7] Hyman, H. T., and Kessel, L.: Archives of Surgery, 1924, viii., 149.

If these claims are corroborated a great advance will have been made; as yet they can hardly be accepted in their entirety. We understand that at the London Hospital this method of pre-operative preparation has been carried out for some time, and the results there obtained are almost entirely in accordance with those published by **FRASER**—that is to say, that there is as a general rule a great improvement following the administration of Lugol's solution, but that a small dose only must be given, the routine dose being ♏ iii. of Lugol's solution three times a day. Moreover, after a short period, often indeed after 10–14 days, the effect of the iodine solution begins to wear off and the patient relapses. If an operation has not been carried out before this the administration must be stopped, when the patient will again begin to improve. If too large a dose is given there has so far always been clear evidence of an exacerbation of the symptoms. This is usually at once shown in the rise of temperature, the pulse-rate, and even in the respirations, so that an estimation of the basal metabolic rate may not actually be necessary. Since such methods of treatment have been tried there has been no post-operative mortality, but in no case, so far, has the care which had previously been exercised in the pre- and post-operative treatment been relaxed. Thus, in no case is an operation performed the day after the patient entered the hospital, as advocated by Dr. **JACKSON**. Each patient is kept in bed for at least two weeks and never allowed home so early as the fifth or sixth day, although it is already evident that the post-operative reaction is very greatly diminished by the administration of the Lugol's solution. It may thus be accepted that the administration of some form of iodine not only gives rise to great temporary improvement in the patient's condition, but it lowers the mortality rate and diminishes the post-operative hyperthyroidism. Whether it will cause so great a temporary improvement that operations can be performed in absolute safety, so that the patient can be allowed back to work as shortly after operation as is claimed by Dr. **JACKSON**, remains for future investigation to decide.

PATENTED MEDICINE.

DURING the past few years we have frequently had occasion to discuss in these columns the broad question of payment for research, and we recently[1] quoted in this connexion the opinions of the National Union of Scientific Workers of Great Britain and of the Privy Council Committee for Scientific and Industrial Research, who alike condemned the rewarding of successful research by money prizes or by the granting of patent rights. Nevertheless, there is at the present day a definite development of the feeling that scientific discovery must eventually be protected against commercial exploitation. Just how this will be brought about is still a matter for speculation, but it is quite possible that some system of patenting, with or without royalties, may be elaborated and brought into action in the future and a fierce controversy will probably rage around these two words. Medical research is obviously to be included under the general heading of scientific discovery, and while any system of patenting seems quite foreign to accepted medical methods, at any rate in this country there have been certain developments within recent years which merit closer attention.

A few years ago the Medical Research Council investigated the various commercial preparations of pituitary extract and found that this valuable drug varied enormously in its potency as supplied by different manufacturing companies. It became obvious that some sort of control was necessary, for such biological preparations are unrecognised by the British Pharmacopœia, since, as the President of the General Medical Council has pointed out, drugs can only be included of which the standardisation can be carried out by a competent chemist. Some biological standards were obviously necessary and their control was handed over to the Medical Research Council in 1921. These standards have been welcomed by the better class of manufacturers who are left free to produce with the minimum of interference as to standardisation. The example of pituitary extract becomes important in view of what subsequently happened in the case of insulin. Here it will be remembered that the University of Toronto patented the name and the process of preparation of insulin, and the Medical Research Council accepted the patent rights in this country as a gift from Toronto. This action was criticised at the time on the grounds that it would limit enterprise and restrict experiments with insulin in this country. In point of fact, it has been abundantly shown by subsequent events that the highest interests both of the public and of the medical profession in this country were being served, for by this action a supply of pure insulin was available for use in circumstances where its action could be watched by competent observers; and on the other hand, exploiters and ignorant or unscrupulous persons were prevented from putting on the market an impure supply of the drug, which would have greatly discredited the reputation of the real insulin. The Medical Research Council has been free from the difficulties of a widely varying commercial supply, as in the case of pituitary extract, and has been able to supervise the production of insulin in a broad and liberal manner. The apprehension which was felt and very freely expressed with regard to insulin was partly due to the use of the word "patent," which conveys the idea of restriction for private gain. It has been suggested that in Germany, where many bacteriological products have been patented, the cost of salvarsan was enhanced by royalties, and in America steps have been taken in some instances by the authors of articles in scientific journals, which might have some commercial value, to protect themselves by applying for letters patent. This seems regrettable, but how else can the public be protected from the commercialisation without due restriction of new lines of research? Some form of protection may be necessary to safeguard the public as well as the researcher.

Perhaps the word "protection" is preferable to "patent" in this connexion, for here they appear to mean much the same. The question of royalties is naturally a thorny one. We gave some account of the possible development of such a system recently[2] when the proposals of Senator **RUFFINI** to the Committee of Intellectual Coöperation of the League of Nations were discussed. From the medical point of view the difference then pointed out which exists between literary copyright and the protection of scientific research is interesting. The hospital physician, for example, may embody the results of his clinical experience in a book for which he will be paid and on the sale of which he will enjoy presumably a certain amount in royalties. No one suggests that such action is contrary to accepted medical ethics. His colleague, the pathologist, who has, we will suppose, no desire to write but who is a brilliant investigator, discovers in the hospital laboratories a specific drug for some hitherto incurable disease. Under existing circumstances some drug house will market this in the interests of the public and naturally at profit to themselves. Although both these men may be remembered by posterity for an equal number of years, this will scarcely compensate for the difference in material reward which they receive during their life-times, a difference which may probably be also appreciable in their respective incomes, even if the hypothetical event had not taken place. Nor is this futile speculation: the problem of the effective protection of the research worker and of some adequate means of rewarding him is one which demands pressing attention, and however objectionable the terms patent and royalties may sound it seems probable that some system of "patented medicine," consistent with the accepted medical principle which puts the interests of the public first, will have to be devised in the not far distant future.

SCIENTIFIC QUESTIONS IN CRIMINAL APPEALS.

When the Court of Criminal Appeal was set up in 1907, Parliament equipped it with power to summon medical assessors and to refer for decision by a special Commissioner any question involving a "scientific examination which cannot in the opinion of the Court conveniently be conducted before the Court." This provision, though the Court was invited to apply it upon the recent appeal of Norman Thorne, has virtually remained a dead letter. The Criminal Appeal Act of 1907 says that the Court may take this course "if they think it necessary or expedient in the interests of justice," and that the reference to special Commissioners shall proceed in accordance with rules of court. The rules were duly made, but have seldom or never been brought into play. They ordain that the Court, in referring any question, shall specify the question exactly and shall name the Commissioner who is to answer it. The order remitting the matter to him may declare what powers (if any) of the Court of Appeal are being delegated. The request for the setting in motion of this machinery in Thorne's case was rather summarily rejected. The application was described as "unparalleled," and, indeed, the whole appeal was dismissed without counsel for the Crown being called upon. The issues which it was suggested should be referred to a special Commissioner were the same medical issues as had arisen at the trial. The questions related to such matters as the existence and significance of marks upon the dead woman's neck, the extent of the pulping of the tissues, the probability or improbability of suicide on the part of an apparently neurotic patient, and so on. What was fatal to the application was just this fact that medical evidence on these very points had been fully given by experts both for the Crown and for the defence at the trial. It may be that juries are not the best tribunals for weighing and judging between the conflicting views of experts, but Lord Hewart has now made it clear that the Court of Criminal Appeal is not going to transfer to a medical referee "the determination of a question on which the jury, with conflicting views before them, has arrived at a unanimous conclusion."

In a proper case, Lord Hewart observes, the Court will use its "special and exceptional" powers of referring scientific questions to a Commissioner. We are left unenlightened as to what conditions will constitute a proper case. There can never, it seems, be a proper case for such a reference on appeal if full medical evidence has been given at the trial. The only occasion, therefore, in which a special Commissioner or a medical assessor is likely to be called in on appeal is the case where medical evidence has been improperly curtailed or rejected by the Court below, or where some medical issue arises unexpectedly after trial. We might perhaps add that the calling in of a medical assessor is the more remote so long as our official experts maintain the excellent tradition of giving evidence with impartiality and detachment, coming to be regarded almost as judicial officers of the Court rather than witnesses for the prosecution.

The Lord Chief Justice gave his judgment in the Thorne case with his accustomed clearness. The fact stands out that, if there is sufficient evidence—whether of a scientific or a non-scientific nature—upon which a jury can convict, and if a jury does convict thereon, the Court of Criminal Appeal is not going to invite anybody else to say whether or not he agrees with the jury's conclusions. The case against Thorne was essentially one for a jury. There was, says Lord Hewart, overwhelming evidence on which they might have returned the verdict they did. Once that fact is accepted, there was really no ground for the appeal, were it not that by a kind of forensic convention an appeal takes place almost automatically in all cases of death sentence. Twice lately Lord Hewart has pointed out, as he did here, that there was nothing in the appeal except the circumstance that it related to a charge of murder. Medical opinion will, we think, admit that the scientific evidence had satisfactory exposition and consideration in the Crowborough murder trial. There is undoubtedly a possibility that, if a jury's decision were lightly to be disturbed either by the Court of Appeal or by a scientific tribunal, juries might be tempted to slur their duties and to abandon the good old tradition of giving the prisoner the benefit of the doubt.

CARDIAC SURGERY ON ANIMALS IN THE FIELD.

A condition described as traumatic pericarditis is well recognised by practising veterinary surgeons. Cattle especially are the subjects of this disability on account of their habit of picking up pieces of wire, knitting needles, nails of various patterns, and other foreign bodies when grazing, and as these foreign bodies are forced along during the act of rumination they have ample opportunity for penetrating the rumen in a particular place, after which they find their way into the pericardial sac, and even to the heart muscle. A number of cases in which foreign bodies have been extracted from the heart of the cow by direct operation are reported by Mr. Leslie P. Pugh in the March issue of the *Veterinary Journal*. A photograph is shown which was taken nine months after such an operation on a very valuable pedigree Guernsey cow, which made an excellent recovery; since the operation she has been giving as much as three gallons of milk daily, and is now again pregnant and in excellent health. To perform cardiac surgery successfully on a farm animal under field conditions is a totally different problem from that of performing it experimentally under the advantageous conditions available in the laboratory, and Mr. Pugh may be congratulated upon the pioneer work which he has done for veterinary science.

Annotations.

"Ne quid nimis."

CICELY NORTHCOTE TRUST.

In a modest little document[1] of 24 pages, issued from the Lady Almoner's Department of St. Thomas's Hospital, is told the story of a side of hospital work which ought to be better known to the public; for it abundantly demonstrates that often the most efficient hospital treatment among the poor neither begins nor ends in the wards. Where help is not given, sometimes before, sometimes after admission, and sometimes at both periods, discharged patients may often drift back to hospital, with the result that previous treatment is wasted, unnecessary expenses are incurred, and deserving patients are kept on the waiting list. The activities of the Northcote Trust are concerned with the adjustment of family life caused by illness, with the provision of surgical instruments and appliances, with convalescent treatment, and with the equally important work of after-care. The report is illustrated by typical cases which speak eloquently for the work being done. One of the most important aspects of this work is connected with a hostel which was opened in 1920 as a home for women and girls suffering from venereal disease. This hostel has accommodation for 14 adults and four infants, and during the past year 44 girls and 16 babies have been in-patients. The aim of the hostel is to create for the visitors a real home where, besides receiving physical healing, the girls may learn something of their responsibilities and privileges as members of a family, neighbours in a community, and citizens. In this connexion it may be noted that Colonel L. W. Harrison recently urged the institution of a home for mothers and babies on their discharge from the V.D hostel from which the mothers could go out to work, leaving the baby under supervision during working hours. The Cicely Northcote Trust coöperates with some 70 other societies and agencies. The work is increasing by reason of the larger number of patients passing through the wards of St. Thomas's Hospital, and is also being added to by new activities of the hospital involving extension in diabetic diets and the provision of insulin. A continuous supply of this drug has been arranged for many patients. Financial help is greatly needed if the growing work of the Trust is to be done as effectively as its importance demands.

CONJUGAL TUBERCULOSIS.

During the last few years many important investigations into the problem of conjugal tuberculosis have been published, and the work of Dr. E. Ward and others has done much to show that, under certain conditions, the risk of infection of one partner by the other is not negligible. This is the lesson of a paper published recently by Dr. H. Tecon in *Paris Médical.* His conclusions are the more interesting as they are based on observations made not only among the institutional patients, but also in his private practice. The number of families studied was 482, and in each one partner at least was sputum-positive. In about 90 per cent. of all the cases husband and wife still shared, or had recently shared, a bed. In 50 per cent. of all the cases the tuberculous husband or wife had not, apparently, conveyed the disease in a clinically manifest form to the other partner, but this immunity was not enjoyed by the children, and as one of Dr. Tecon's family histories shows—and he records it as an example typical of many—the chances of husband or wife infecting the other partner are very much less than the chances of a tuberculous parent infecting one or more of the offspring. The chances of conjugal infection are certainly not small to judge by the following figures. In as many as 90 of the families investigated, there was evidence of the one partner having been infected by the other. In another 17 cases, infection of one partner by the other could not be so clearly proven as there were other possible sources of infection. Of the 90 cases already referred to, as many as 63 were cases of infection of the wife by the husband—in other words, as great a proportion as 70 per cent. of all the cases of proven conjugal tuberculosis represented infection of the wife by the husband. This sex difference in the risk entailed by marriage with a consumptive would seem to depend on many factors, chief among which may be the wife's seclusion throughout most of the day to the infected house; the husband in most cases spends a relatively short period of the 24 hours at home. Another factor which Dr. Tecon omits to discuss in this connexion is the wage-earning capacity of man and wife respectively; if the first partner to develop tuberculosis is the husband, the daily bread of the couple will usually be more reduced than would be the case had the wife been the first to develop this disease. A comparison of the course of the disease, according as it was conveyed by husband to wife or by wife to husband, did not indicate any great differences, and it is noteworthy that, only with rare exceptions, the site of the disease in the second partner was also the lungs. Turning from the statistics, Dr. Tecon discusses their application to the problem with which a medical man is confronted when his opinion is invited on a prospective marriage one potential partner to which is tuberculous. Dr. Tecon is wise enough not to generalise, and he recommends the discrimination which judges each case on the particular circumstances involved.

PATHOLOGY IN GENERAL PRACTICE.

The evils resulting from the lack of coöperation between the clinician and the pathologist are common subjects of discussion in most enlightened medical circles, but unfortunately the conversations seldom lead to any attempt to rectify the situation. In general practice in this country pathology means little more than routine examinations of blood, sputum, urine, and so forth. Only very rarely are post-mortems done in private practice, which is merely another way of saying that, except in some cases where a surgical operation is the penultimate event, the ante-mortem diagnosis is only very rarely controlled. In this matter America appears to be leading the way, for in a recent number of the *Medical Journal and Record* Dr. W. W. Waite,[1] of El Paso, Texas, reports the formation of a small society for the study of pathology by general practitioners, the objects of which deserve high praise.

Dr. Waite and his colleagues, realising that medicine cannot be scientifically followed if divorced from pathology, have formed among themselves a small group for the purpose of performing autopsies on patients dying in their practices, and for studying the material obtained thereby. The group is limited to about a dozen members, for it is felt that this is the largest number which can work round a body and see all there is to be seen, and can meet together regularly for close study. The organisation of the group is quite loose—there are no officers, though the pathologist acts as director—each member does what he can to serve the common object, and with increasing experience becomes capable of performing autopsies for himself and carrying out the further necessary investigations. Time being of importance, only brief clinical histories are given at the actual autopsies, but at the regular meetings the cases are discussed in detail. Full clinical histories are given, the pathological findings are carefully scrutinised, and microscopic preparations are projected on to a screen, a part of the proceedings which has proved to be extremely popular. The best specimens are saved, and a museum is being formed which, it is believed, will be of real educational value. At these meetings discussion is free and pointed. Good work may be commended, but imperfect clinical histories and faulty observations are criticised without restraint. The material has been surprisingly interesting and varied, far better, the reporter states, than any he saw in hospital, and upwards of a hundred autopsies have been performed in the six months during which the organisation has been properly developed.

---

[1] Cicely Northcote Trust: Fifteenth Annual Report, October, 1923, to October, 1924.

[1] Home Post-graduate Work by Means of Post-mortem Examinations, Med. Jour. and Record, Feb. 18th, 1925.

There is no better way to study medicine than to keep good records of cases and, when the patients die, to examine the body. Why, then, is this not more often done? In this country, at any rate, local conditions may be largely to blame. Autopsies are not easy to carry out in general practice; Dr. Waite himself confesses that in American homes it is difficult to obtain leave for their performance. But in America embalming is usual, and undertakers' establishments have to be equipped with good operating theatres which are convenient places for making the post-mortem examinations. This, however, cannot be the whole story, for by no means all the patients dying in our hospitals, even the teaching institutions, come to the post-mortem room, and the fault does not lie entirely with the general public. It is true that in a certain proportion of cases permission to make an examination is refused, but when the doctor takes the patient's relations into his confidence and explains the situation, this proportion becomes surprisingly small. The general public, no doubt, needs educating in these matters, but the medical profession is perhaps not beyond reproach. We may at any rate congratulate Dr. Waite and his friends on their achievement, and the medical schools from which they graduated on the success with which they have imbued their graduates with the true scientific spirit. Mr. Lewis Sinclair, please note.

PATHOGENICITY OF THE BACILLUS ABORTUS IN MAN.

AT a recent meeting of the Royal Society of Medicine[1] Prof. J. H. Eyre introduced a discussion on the alleged identity of the *Bacillus abortus* of Bang and the *Micrococcus melitensis* described by Bruce. Their morphological, cultural, and serological identity is well known, the striking difference between one micro-organism and the other lying, according to some observers, in their pathogenic power with regard to man—namely, that *B. abortus* is devoid of such power. Nicolle, Burnet, and Conseil made numerous experiments in this direction and inoculated five subjects with cultures of *B. abortus*, three derived from cows and two from swine. None of these individuals presented any febrile or other disturbance. According to Nicolle, the absence of pathogenicity of *B. abortus* for man would exclude infection by this organism, but further confirmation is required on this point. In the actual state of our knowledge it may probably be concluded that we do not possess data of differentiation enabling us to distinguish *B. abortus* from the *Micrococcus melitensis*; hence we cannot say certainly whether a patient, from whose blood a micro-organism is isolated which responds to the tests for both germs, is affected by one of them rather than the other. We may refer to clinical observations of cases recently verified in the provinces of Bologna, Ferrara, and Modena, in which it has not been possible to trace in the history of the patients any contact with goats, and may consider, moreover, that these cases occurred coincidently with an epidemic of epizootic abortion and were not rare in veterinary surgeons and butchers who had been in contact with affected cows. It is of interest to draw attention to two cases published by Dr. R. Viviani.[2]

> The first case was that of a butcher, aged 35, whose cows in one stall had all aborted. Fifteen days previous to being taken ill he had slaughtered a sick calf in this stall. His illness consisted of fever of remittent type accompanied by sweating and splenic enlargement. He had had no contact with goats; in fact, there were none in the neighbourhood. Malarial parasites were absent from his blood, the leucocytic formula of which was normal. Agglutination for typhoid and paratyphoid was negative, that for melitensis occurred in dilution of from 1–700 to 1–1000, that for *B. abortus* 1–1000. Cultures revealed a small coccus and a short bacillus Gram-negative. The serum agglutinated this germ at 1 per cent. Agglutination also occurred with 1–1200 antimelitensis serum and with 1–1000 serum of cows affected with abortion, which also agglutinated *B. abortus* at a dilution of 1–800.

The experiments of W. E. Cotton, published in the *American Veterinary Review*, December, 1923, would seem to show that a large number of abortions in pigs were related to an aberrant type of *B. abortus*, the specific agent of contagious abortion in cows, and in this connexion the second case reported by Dr. Viviani is interesting.

> The patient, a previously healthy girl, had never drunk goats' milk nor come directly in contact with them. There had been no cases of epizootic abortion in her stalls, but she had looked after a sow which had aborted some months previously. Her febrile attack lasted about two months and was accompanied by enlargement of the liver and spleen. Malarial parasites were absent and sero-agglutination occurred with melitensis in dilutions of 1–1000 and also with *B. abortus*. Notwithstanding the absence of fever at the time of examination a Gram-negative organism was isolated morphologically similar to *Micrococcus melitensis* and agglutinated by 1–1200 antimelitensis serum and by 1–1000 serum of cows affected with epizootic abortion.

The importance of the question evidently calls for further experimental researches.

WOUND TREATMENT BY SUCTION.

AN article in the *Schweizerische Medizinische Wochenschrift* (Jan. 29th, 1925) by Chas. Reinert, of Bern, deals with the uses of suction in combination with irrigation in the after-treatment of suppurating wounds and cavities. The principle underlying the treatment consists in the continual slow irrigation of the wound with some suitable antiseptic or saline lotion, and the immediate removal of the discharges by slow continuous suction. The apparatus used consists of two independent parts arranged on the same stand, the one for irrigation and the other for suction; either may thus be used separately when the combination is not required. The suction part of the appliance bears some resemblance to the Cathcart pump for use after cystotomy, and consists of two large glass bottles connected by a drip-feed to regulate the flow from the upper to the lower. The suction tube is attached to the top of the upper vessel and is led to the wound via a smaller collecting bottle. By means of a by-pass valve the used water in the lower bottle can be pumped by hand into the upper vessel again and the suction thus made continuous. In addition, the author has modified Bier's suction glasses in such a manner that the wound is irrigated and the discharges withdrawn, while a negative pressure is kept up within the chamber the whole time. By attaching this apparatus to a small glass cup from which a tampon of gauze extends down into the depths of the wound he has also been able to combine suction with capillary attraction. The total energy available is very small, and, as can easily be appreciated, the negative pressures produced are low and equal only 2 or 3 inches of water. The author considers that the latter is an advantage as no possible damage to delicate granulation or other tissue can occur. At the same time it must be borne in mind that the discharges from wounds are oftentimes thick, fibrinous, and viscid, and, even although the irrigating fluid may thin them to some extent, a negative pressure of a few inches of water only will be insufficient to move them along the collecting tubes. Again, if there be the slightest air leakage around the sides of the wound no suction will be exerted upon the discharges and the apparatus will merely aspirate air. The author makes the suggestion that where more rapid suction is needed the water be allowed to flow freely from one bottle to the other by short circuiting the drip-feed. This can only be used during the actual dressing of the wound, for the increased degree of suction must of necessity be of short duration. The use of low degrees of suction in the continuous drainage of wounds bears little relationship to the use of suction in actual operative work. Here the degree of suction must be considerable in order to remove thick discharges, and especially blood, from the field of operation. The total amount of energy available, too, must be large if the blood is to be removed rapidly enough to be of real assistance to the operator. These desiderata cannot be achieved by a pump such as the one described by Reinert, but may be met by especially designed pumps drawing their energy from the electric supply, such as the reciprocating and rotary pumps, from the water-supply, as in the Sprengel pump, or cylinders of compressed gas, as in Norman Lake's pump described in The Lancet (1924, ii., 1166). Each of these will work satisfactorily, and the choice of pump ultimately depends chiefly upon portability, ease of operation, and expense. As would be expected, however, none of these operating pumps are suitable for the continuous drainage of wounds or cavities. A small pattern of Lake's pump has, we understand, been made to work for one hour off a 60-gallon cylinder maintaining a negative pressure of about 10 inches of water, but even so the expense and frequent changing of cylinders render it unsuitable for really continuous suction. For this purpose, therefore, the pump described by Reinert may be of value. While operative suction is a method which is being used more and more extensively by workers in every branch of operative surgery, the question of the real advantages to be derived from continuous irrigation-suction over other methods is one about which many will still be inclined to reserve judgment.

INTERSTITIAL KERATITIC NODULES IN TRACHOMA.

From the ancient capital, Zagreb, we have received a special number of the journal of the Medical Society of Croatia and Slavonia, celebrating the jubilee of its foundation in 1874, and claiming by implication for the new State of Jugoslavia its due place in the scientific and medical world of the West. The title alone of the journal (*Lijecnicki Vjesnik*) is unintelligible to those without the language, for the articles, of which there are 16, are in either German, English, or French. They include clinical studies of diabetes insipidus, a description of a case of thrombosis of the lateral sinus after peritonsillar abscess, notes on the intermediary zone in the spinal cord of mammals in relation to the visceral nervous system, and a discussion of the statistics of eclampsia. The restoration of the ala nasi is the subject of a sound note, and a case of mixed spring catarrh and trachoma with nodules in the parenchyma of the cornea demonstrable by the slit lamp is described. By direct light, on magnification about 55, these nodules were seen as greyish bodies "of poppy corn size," but they were seen better by reflected light as very fine black dots. They ultimately cleared up after treatment with copper, leaving the vision nearly normal. The author, Dr. V. Derkac, claims that this particular change has never been previously described in connexion with trachoma.

ANTITOXIN INTRAPERITONEALLY INJECTED.

Dr. John A. Toomey, Dr. Otto L. Goehle, and Dr. Carl C. Dauer, of the Division of Contagious Diseases, Cleveland City Hospital and the Department of Pediatrics, Western Reserve University, record their observations[1] on 168 cases of diphtheria treated by intraperitoneal injections of antitoxin with comparative observations on 100 other cases of diphtheria, 50 of which received antitoxin intravenously and 50 by the intramuscular route. The only previous series of diphtheria patients on record treated by intraperitoneal injection of antitoxin consist of 12 cases reported by Dr. E. S. Platou, of New York, to whose paper we drew attention at the time.[2] Like this observer, the present writers found the intraperitoneal method was a safe and simple one, and further simplified it by using commercial antitoxin without the addition of saline solution. The injection was received well in all cases. Only one patient with no history of protein sensitivity had a violent reaction which began five minutes after injection and lasted ten minutes. In five other patients menstruation started again, but no other undesirable effects were noticed. The clinical evidence pointed to rapid absorption of the antitoxin by the peritoneum. The membrane disappeared almost as quickly after intraperitoneal injection as when the intravenous method had been used, without the disagreeable reactions associated with intravenous injection. While not recommending intraperitoneal injection for all cases of diphtheria, the writers regard it as the method of choice in cases of toxic myocarditis where it is desirable to avoid the shock accompanying intravenous injection, and also advise its employment in infants and children with poorly developed veins who have had diphtheria for more than two days.

WELFARE WORK IN THE UKRAINE.

Under the heading the Care of Mother and Child in the Ukraine, with especial reference to the City of Kharkov, the *Brazil Medico* for Nov. 29th, 1924, publishes an article of considerable interest by Herr Friedel Haustein, of Berlin. The author states that on a tour of investigation through Russia, undertaken on behalf of the Section of Hygiene of the League of Nations, he was very favourably impressed by the excellence of the arrangements made for the welfare of mother and child, as also by the satisfactory physical condition of the children, both those in institutions and those outside. A detailed description is given of the system at work in the Ukraine with its antenatal clinics, infant welfare centres, creches, arrangements for the treatment of crippled children, those suffering from tuberculosis and venereal disease, and for the general hygienic supervision of school-children up to the age of 16. As the means at the disposal of the State are very limited, all superfluities are dispensed with and the greatest simplicity is observed in the institutions engaged on the work; at the same time, states the author, mean economies are avoided and the just requirements of hygiene are uniformly met. Special mention, says Dr. Haustein further, should be made of the altruistic devotion and enthusiasm for the work exhibited by all the medical men engaged in it. This continually impresses the observer and explains how it has been possible throughout the Ukraine to build up from nothing and with the scantiest means the equipment necessary for the carrying out on a grandiose scale of the present Government scheme for the protection of mother and child.

ADENOMYOMA OF THE STOMACH.

Small pieces of pancreatic tissue are not very uncommonly found in irregular places detached from the main gland altogether. They are usually situated in the wall of the stomach, duodenum, or jejunum, and may rarely form the starting points of carcinomata; generally they remain quite small and are of no evident practical importance. A group may, however, be differentiated which are larger, more complex in structure, and associated with symptoms which make it possible that the surgeon may come across them; their recognition, then, is desirable, since they are in no sense malignant and are satisfactorily treated by local removal without anything drastic in the way of gastrectomy. The current number of the *Journal of Pathology and Bacteriology* (vol. xxviii., p. 195) contains a well-illustrated account by Prof. M. J.

---

[1] American Journal of Diseases of Children, February, 1925.

[2] The Lancet, 1923, ii., 994.

Stewart and Dr. A. L. Taylor, of Leeds, of five cases which they have met with, one at post-mortem, the others at operations. Where clinical details were available, there was a history of intermittent dyspepsia over periods varying from two to 16 years; pain of the hunger type and nausea were present, but no vomiting or hæmatemesis. Removal of the nodule cured the symptoms. These adenomyomata occur as thickened plaques in the stomach wall in the neighbourhood of the pylorus, about half to one inch in diameter, covered with normal mucosa; section shows a localised hypertrophic thickening of the muscular coat with a whorled arrangement; one or more small cysts are also often present. Microscopically, undifferentiated epithelium occurs in acini or ducts which more or less resemble bile or pancreatic ducts, while fully differentiated Brunner-type glands on the one hand and pancreatic acini on the other are also found. Mingled with these epithelial elements, and often forming definite sheaths to the glandular masses, is overgrown smooth muscle which evidently forms an integral part of the abnormality. The condition has no relation to ulcer or carcinoma, and is one of those heterotopias which, as Dr. G. W. Nicholson has shown so well in recent volumes of the Guy's Hospital Reports, throw such interesting light on the problems of growth and differentiation.

TUBERCULIN TESTS IN CATTLE: THE INTRADERMAL TEST.

THERE is issued this week a report[1] of the Tuberculin Committee of the Medical Research Council dealing with tuberculin tests in cattle and having special reference to the intradermal test. The Tuberculin Committee was appointed five years ago to direct investigations into the use of tuberculin in the diagnosis and treatment of human tuberculosis, at which stage the medical members of the Committee shared the general opinion that tuberculin tests, and in particular the subcutaneous tests, were of proved utility for the diagnosis of tuberculosis in cattle, however limited their value might be in the human subject. Shortly afterwards representations were made to the Ministry of Health by Lord Astor, Lord Elveden, and Mr. Wilfred Buckley, showing that the tuberculin tests made in herds producing "certified milk" gave anomalous results, and, as many other stock owners have found the same, the Ministry of Health sought the assistance of the Medical Research Council, within whose province further investigations obviously lay. The problems which the Committee had before them on commencing these investigations were to account for discrepancies in reaction to the subcutaneous test, to ascertain the comparative values of the tests—whether subcutaneous, intradermal, or ophthalmic—and to suggest the most efficient varieties of tuberculin and improvements in the methods of standardisation.

The Committee, of which Captain S. R. Douglas is the chairman and Dr. Salusbury MacNalty is the secretary, came to the following conclusions, among others:—

(1) That the subcutaneous test is perfectly satisfactory for the presence of tuberculosis in cattle, when carried out under the laboratory conditions of a scientific trial, though it may be unsatisfactory in ordinary farm conditions.

(2) That the intradermal test is superior to subcutaneous tests, the ophthalmic test being regarded as subsidiary.

(3) Of the intradermal test it is stated that it is an accurate test for the presence of tuberculosis in cattle, the percentage of error being extremely small, while (4) its further advantages over the subcutaneous test are, no need for temperature observations, no need to rest the animal, or interfere with the ordinary routine treatment; three observations only are usually necessary; and a smaller quantity of tuberculin is needed.

(5) The variety of tuberculin employed is "Old Tuberculin," and it appears to be immaterial whether a bovine or human strain is used; but (6) it should be of proved high potency, being administered undiluted for both intradermal and ophthalmic tests.

Prof. G. Dreyer and Mr. R. L. Vollum, working for the Tuberculin Committee, published in THE LANCET last November[2] a paper on the Precipitin Method for the Standardisation of Old Tuberculin, an abstract of which is given in the report. While the Committee conclude that extremely accurate standardisation may later be found unnecessary, they hold that no tuberculin should be employed in the examination of cattle that has not been tested by some method to show that it is of high potency.

THE OPHTHALMOLOGICAL SOCIETIES' CONVENTION.

THE Ophthalmological Society of the United Kingdom, together with its affiliated societies, has decided to hold in London, from July 14th to 17th, a Convention of English-speaking ophthalmological societies and associations, all members of which are invited to attend, and the presidents of such bodies in the different parts of the British Empire and the United States of America have been asked to appoint official delegates. Mr. E. Treacher Collins will preside over the Convention, and an interesting programme has been arranged. Four mornings, two afternoons, and one evening will be devoted to the scientific work of the Convention. On Wednesday evening, July 15th, there will be a symposium on the subject of the Evolution of Binocular Vision by the following selected speakers: Sir Charles Sherrington, P.R.S., Sir Arthur Keith, F.R.S., Sir Frederick Mott, F.R.S., Prof. Elliot Smith, F.R.S., and Prof. S. E. Whitnall. The Bowman Lecture will be delivered by Sir John Parsons, F.R.S., on the afternoon of Thursday, July 16th. Microscopy of the Living Eye has been chosen as a subject for discussion. It will be opened by Dr. Gordon Byers, Montreal; Dr. Arthur J. Bedell, Albany, U.S.A.; Mr. Harrison Butler, and Mr. Basil Graves. Those wishing to take part in it, to read any paper, or exhibit any specimen at the Convention should send in their names to the secretary of the Scientific Business Committee, Mr. R. Foster Moore, 91, Harley-street, London, W. 1, not later than four weeks before the meeting. At a general meeting of the Convention the re-establishment of international ophthalmological congresses on the pre-war basis will be considered. There will be a museum of drawings, instruments, pathological and anatomical specimens, to which all members of the Convention are invited to send exhibits. The General Secretary of the Convention is Mr. C. B. Goulden, 79, Portland-place, London, W. 1, from whom further particulars may be obtained.

ROYAL NORTHERN (GROUP OF) HOSPITALS.—The annual report of this group, which includes the Royal Chest Hospital and the Hospital of Recovery at Southgate, together with the Convalescent Home at Clacton-on-Sea, shows that during 1924 32 closed beds were reopened, though 28 still remain closed. The number of in-patients treated was 4801 and out-patients 40,834, an increase in both departments on the previous year. The financial report is very satisfactory; donations amounted to £30,847, as compared with £24,975 in the previous year, and legacies to £7950, as against £2634 in 1923. The total income for maintenance purposes was £82,720, as compared with £73,951 in the previous year. The report states that the number of patients attending the light treatment department has so increased that it has been necessary to extend it, and that a new maternity department will be worked in conjunction with the Maternity Nursing Association, while arrangements are being made for the interchange of nurses and pupils for training in midwifery. In the venereal diseases department an additional session for women and children was arranged. During the year 848 new cases of venereal disease were treated, and the total number of attendances was 14 697.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

CXVIII.—THE TREATMENT OF SYMPTOMLESS HÆMATURIA.

Under this term is included a group of cases characterised by the presence of hæmaturia as the only symptom or sign of which the patient complains —pain, frequency of micturition, pyuria, and other symptoms so frequently associated with bladder or kidney troubles being here conspicuously absent. Pain, however, may occur in symptomless hæmaturia if the bleeding be profuse enough for clots to form and to pass along the ureter or urethra, but such pain is merely an accident in the case, and is not dependent upon the actual cause of the hæmaturia. The hæmaturia is usually simply a chance discovery on the part of the patient, who happens to notice the altered colour of the urine.

Hæmaturia of this symptomless type may arise from a great diversity of pathological conditions—in fact almost any disease of the urinary tract may occasionally so first declare itself, though with most of such it is very exceptional. In 1922 I analysed 100 cases that had come under my own observation to ascertain the pathological conditions ultimately disclosed. The hæmaturia was of vesical origin in 65 (the commonest single cause being villous papilloma, 41 cases) and of renal origin in 35 (malignant growths, including hypernephroma, being the most frequent cause). In 86 cases the pathological cause was definitely ascertained, and of these 71—i.e., 82·5 per cent.—were due to neoplasm (44 benign and 27 malignant). Thus of all my cases of symptomless hæmaturia of known ætiology benign neoplasm accounted for 51·1 per cent. and malignant neoplasm for 31·3 per cent. This great preponderance of new growths will naturally lead the surgeon to think first, in any given case, of neoplasm, and especially of villous papilloma of the bladder; the fact, however, that in about one-third of all cases a malignant growth is present, possibly in an early and operable stage, should emphasise the extreme importance of tracing the hæmaturia to its source at the earliest opportunity. In my series, among the rarer causes of vesical origin were included prostatic enlargement, simple "solitary" ulcer, and calculus fixed in a post-prostatic pouch; of renal origin papilloma of the renal pelvis, angeioma of a renal papilla, renal calculus, congenital cystic disease, chronic nephritis, mobile kidney, and "essential" hæmaturia. This term is applied to renal hæmaturia, the ætiology of which cannot be determined even after the application of all the methods of urological investigation at present known. It is an astonishing, and at the same time a disconcerting fact that, as in two of my cases, a kidney may bleed so profusely as to necessitate nephrectomy to prevent immediate death from hæmorrhage, and yet subsequent examination by an expert pathologist may fail to discover any macroscopic or microscopic change in it.

Investigation of a Case.

The first step in the clinical investigation of a case of symptomless hæmaturia is to make sure, by microscopic detection of blood corpuscles, that it is really hæmaturia, and not the rare condition of hæmoglobinuria. Further, general diseases that cause hæmaturia such as scurvy-rickets, hæmophilia, the group of anæmias, and the passive congestion of heart disease, must be excluded. Next must be investigated, in order of urgency, (1) the source of the bleeding, whether vesical or renal, and if the latter whether unilateral or bilateral, (2) the nature of the lesion causing it, and (3) the functional state of the rest of the urinary tract. The physical characters of the blood—whether intimately mixed or not with the urine, whether bright red or darker in colour, and whether associated with clots of any characteristic shape—although serving as a rough-and-ready guide to the source of the hæmorrhage, are not sufficiently trustworthy in any given case. By cystoscopy alone can the source of the hæmorrhage be determined with certainty, and its application, particularly if bleeding is actually in occurrence, should be regarded as a matter of extreme urgency. If the hæmaturia be of renal origin, it is only at this time that it can be traced to the defaulting kidney; it may last but a few hours, and may not recur for many months, during which, in about one-third of all cases, a malignant growth will be steadily progressing, and its chance of successful removal becoming lost. It still happens much too often that the practitioner's first efforts are directed not to the ascertainment of the source of the bleeding but to its immediate arrest; he puts the patient to bed and administers morphine and internal styptics. Although this may allay the alarm which many patients feel, in the long run it will prove the greatest possible disservice: it is far better to let the hæmorrhage continue until arrangements can be made for a cystoscopic examination to trace it to its source.

The Need for Cystoscopy.

Cystoscopy is as urgently called for in this type of case as is early laparotomy in acute abdominal crises. Cystoscopy during bleeding will, if this be of renal origin, show from which ureteric orifice the blood is escaping; if the bleeding is of vesical origin and not too profuse completely to prevent vision, both the source of the hæmorrhage and the causative lesion will be seen. If it be very profuse, repeatedly washing out the bladder with hot boric lotion, combined with the introduction of a solution of adrenalin, will usually suffice, but if these measures fail to secure satisfactory vision, then this fact alone is strong presumptive evidence of a vesical origin, and is sufficient justification, should the hæmorrhage be alarming, for immediate suprapubic cystotomy. Cystoscopy, after cessation of the hæmorrhage, may fail to show its source. Should it have been of vesical origin some lesion in the bladder sufficient to account for the hæmorrhage will be noted; the absence of such lesion indicates a renal source, though it does not indicate which kidney is at fault. If one ureteric orifice has a definitely abnormal appearance, this suggests, though it does not prove, that the corresponding kidney is the offender; no proof is, in fact, possible, save actually seeing the bleeding in progress, and this should emphasise the importance of not permitting the bleeding stage to pass without a cystoscopic examination. Thus in one case cystoscopy, after hæmorrhage had ceased, showed a large villous papilloma of the bladder, which might well have been a sufficient cause; later cystoscopy, however, during bleeding, showed blood coming from the left ureteric orifice, and renal exploration disclosed a hypernephroma. In another case, one of right renal calculus shown by previous radiography, was admitted urgently into the Manchester Royal Infirmary with severe right renal colic and profuse hæmaturia. The latter was thought, not unnaturally, to be due to the calculus; routine cystoscopy, however, traced the blood to the left ureteric orifice, and later exploration of the left kidney again disclosed a hypernephroma. If the bladder be normal and no renal tumour or other physical sign be discovered, then there is nothing for it but to wait until the hæmaturia recurs and cystoscope during the attack.

Bleeding from the Kidney.

When the blood has been seen to escape from one ureteric orifice, a thorough investigation must be instituted by all the usual urological methods to ascertain, if possible, the pathological lesion in the corresponding kidney—careful palpation of the loin, a chemical, microscopic, and bacteriological examination of the urine, and possibly also of the separated urines after ureteral catheterisation, radiography, and pyelography. By these means positive evidence may be obtained of certain conditions—e.g., calculus, tumour, or tuberculosis—but if they yield negative evidence only an exploratory nephrotomy should always be performed. Only when this has been undertaken with negative result do I care to regard the hæmorrhage as "essential." American writers apply the label "essential" when urological investigation short of exploratory nephrotomy fails to show a cause, and advocate expectant treatment of "essential" hæmaturia—intrapelvic injection of silver-nitrate solution through the ureteral catheter, the administration of calcium salts by mouth or intravenously, the subcutaneous injection of horse-serum, &c. I would fear in these cases that an early malignant growth was possibly being overlooked. This would certainly have happened in the two earliest malignant renal growths I have operated upon, which were discovered only after operative exposure, and the patients are both well four and a half and two years respectively after nephrectomy.

Before undertaking operative exposure of the kidney it is necessary, inasmuch as it may disclose some pathological condition requiring nephrectomy, that the functional capacity of the opposite kidney be estimated. For this I rely most upon the indigo-carmine test, the dye being injected intravenously, when the appearance of a deep-blue efflux at the ureteric orifice within three to six minutes is a safe indication of good renal function. Where the opposite kidney is efficient the bleeding organ is exposed from the loin, the upper end of the ureter and the pelvis carefully examined by palpation from without, the renal pedicle temporarily compressed with a light clamp, and the renal parenchyma freely incised a little posterior to its coronal plane until the pelvis and calyces are widely opened. If no macroscopic lesion be found, a small slice of the parenchyma is removed for microscopical examination, and the kidney carefully sutured with deep and superficial catgut sutures. The case must now be classed as one of "essential" hæmaturia, and should the hæmorrhage recur it may be treated expectantly with the confidence that a malignant growth has not been missed; only should the hæmorrhage become so profuse as immediately to threaten life should further operative treatment—i.e., nephrectomy—be considered.

ARTHUR H. BURGESS, F.R.C.S. Eng., M.B., Ch.B., M.Sc. Vict.,
Professor of Clinical Surgery, University of Manchester;
Hon. Surgeon, Manchester Royal Infirmary.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdrs. to be Surg. Comdrs.: H. B. Parker and J. L. Priston.

TERRITORIAL ARMY.

Capt. G. F. R. Smith to be Maj.

Capt. C. W. Healey (late Gen. List T.A.) to be Lt., and relinquishes the rank of Capt.

TERRITORIAL ARMY RESERVE OF OFFICERS.

Maj. P. R. Bolus, from Active List, to be Maj.

ROYAL AIR FORCE.

D. B. Smith is granted a short service commission as Flying Officer for three years on the Active List.

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 4TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—Small-pox, 152; scarlet fever, 1713; diphtheria, 864; enteric fever, 42; pneumonia, 1449; puerperal fever, 54; cerebro-spinal fever, 8; acute poliomyelitis, 7; encephalitis lethargica, 56; dysentery, 10; ophthalmia neonatorum, 111. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases showed an increase of 18 over the number for the preceding week.

Deaths.—In the aggregate of great towns, including London, there were 5 deaths from enteric fever, 125 from measles, 11 from scarlet fever, 117 from whooping-cough, 29 from diphtheria, and 242 from influenza, as compared with 281, 304, 283, and 361 in the four preceding weeks. In London itself the deaths from influenza numbered 38, from whooping-cough 32, and from diphtheria 7.

THE GOLD TREATMENT OF TUBERCULOSIS.

PRELIMINARY REPORT BY THE MEDICAL RESEARCH COUNCIL.

I.

VARIOUS gold compounds have from time to time been used in the treatment of tuberculosis. Recently a soluble complex salt of gold and sodium—namely, sodium aurithiosulphate—which has long been known to chemists, and is now made available under the trade mark of "Sanocrysin," has been introduced to therapeutics as a treatment for tuberculosis by Prof. Möllgaard of Copenhagen, who has found that it has the advantage of dissociation into complex-ions so that toxicity due to free gold-ions is avoided. Such toxic effects as this compound produces in tuberculous but not in normal subjects are attributed to destruction of the bacilli and increased liberation of tubercle toxins; and Prof. Möllgaard has also prepared an antitoxic serum for use, when necessary, to counteract these ill-effects. The results of experiments on animals and of numerous trials on human patients in some Danish hospitals have been fully described in his book, autumn 1924, on the "Chemotherapy of Tuberculosis." Critical summaries of these results and of other work in Denmark have been published recently in *The Lancet* and in the *British Medical Journal*. Clinical trials are now proceeding also in Germany and in Canada.

Prof. Möllgaard very courteously gave to the Medical Research Council a full supply both of the gold salt and of the protective serum for clinical trial in England, but desired that the preparations should not be made available for general use in medicine until the results of these trials were completed. In December he and his chief clinical colleague, Dr. Secker, visited England and gave a personal communication on the subject to those who were asked to try the preparations; while Dr. Secker remained in London long enough to visit several hospitals, advise on the selection of cases, and give the observers invaluable help during the treatment of individual patients by instruction drawn from his own wide experience.

The preparations were issued by the Council, as on the similar occasion of the introduction of insulin to therapeutics, only to those who were not engaged in private practice—that is, to whole-time professors of medicine or to tuberculosis officers. The Ministry of Health were kept in close touch with the work through a liaison officer. On account of the general interest aroused by discussion of this method of treatment, the Council think it desirable to issue this preliminary report on the early results of cases so far treated in Great Britain, and to explain their further policy.

Work in England has been in progress for less than three months; it has not been on a large scale, but the value of the opinions formed has been enhanced by the arrangement which used several observers of small groups working at first independently of each other rather than one observer of a large group. It was evident, when the observers subsequently met in the first conference upon which this report is based, that there was so great a divergence of opinion upon the value of the drug that any single observer relying solely on his own experience might easily have been led to a summary opinion that would have been unduly emphatic in his judgment for or against the treatment. The report deals solely with clinical results, and does not consider the laboratory evidence for the effect of the gold salt on tubercle bacilli or infected tissues nor that for the protective action of the specific serum.

Each dose of sanocrysin was dissolved in 10 c.cm. of distilled water and injected intravenously. The usual amount was 0·5 g. for the first injection and then repeated injections of 1 g. each at intervals of about three days, unless a severe reaction on the part of the patient occurred and compelled delay until the reaction had subsided. The total amount used in any case was generally about 5 or 6 g., and the injections were rarely continued until the goal suggested by the Danish experiences was attained—namely, a final state in which the last injection produced no rise of temperature.

The specific serum, usually from horses immunised by diaplyte tubercle vaccine, though at first a weaker calf serum also received trial, was injected into the muscles in doses of 20 c.cm. Its action is supposed to be that of neutralising the flood of tuberculous toxins liberated by the action of the gold salt on the infected tissues, and thus of lessening the general severity of the reaction to the chemotherapeutic injection. In cases with heavy tuberculous infection the serum was used either before or together with the first gold injection as a preliminary measure. In mild cases it was not used until a reaction of some severity had occurred; and in many instances it was never used at all.

Effects of the Injection of Sanocrysin.

Vomiting was often noticed as an immediate effect within a few minutes of the injection. In one control patient, without evidence of tuberculous disease, there was nausea and prolonged anorexia after three injections but no temperature rise or any other reaction. There were no other control observations of cases with fever from known causes other than tuberculosis, so that the evidence is not sufficient to ascertain whether the gold salt can be used as a test to distinguish non-tuberculous from tuberculous febrile states. In a group of five cases of pulmonary tuberculosis, that were clinically mild but radiologically moderately extensive, there were slight pyrexia and trifling albuminuria, but no other features of reaction. The gold salt in amounts up to 5 or 6 g. therefore seemed to be non-toxic for patients with only slight tuberculous lesions.

Severe reactions were generally produced in cases of more extensive infection. The temperature rose within a few hours to 103° or 104° F.; but there was no case of hyperpyrexia nor of critical fall. Vomiting often recurred, but diarrhœa was not often observed. The patient felt ill, depressed, and lost appetite. A metallic taste was sometimes complained of, and there was a tendency to ulceration of the mouth and throat. The rise of temperature lasted three or four days, but was generally less with each successive dose. After the second or third dose rashes often appeared, like those of measles or scarlet fever, and not often itching. In one case an erythematous rash persisted for a fortnight and was accompanied by an outbreak of many indolent open sores. The rashes were seen in cases where no serum had been given. They were perhaps more frequent in cases of closed tuberculous infection.

Albuminuria was a common occurrence, and in some cases exceeded 1 per cent., though it did not last long. No œdema resulted and there was no evidence of persistent renal lesions. Measurements of blood-urea were not made in any of the cases of severe albuminuria. In one necropsy, where there had never been more than trifling albuminuria, 8 per cent. of the total metallic gold injected was found in the kidneys on death 28 days after the last injection of sanocrysin. Gold was proved to be excreted by the bowels and by the kidneys after an injection of sanocrysin. Jaundice of a grave nature, which in the Danish experience was a very rare event, occurred in another patient who died, and a relatively large amount of gold was found on analysis of the liver.

Features strongly suggesting that the gold salt had a direct action at the site of the tuberculous infection were often seen. Thus, in the lungs a focal reaction was evidenced by local pain, a sense of tightness, and by prolonged tachypnœa. This was in at least three instances aggravated by the development of a very critical state in which the pulse became rapid and feeble and the patient so collapsed, though the temperature did not fall seriously, that great anxiety was aroused as to the chances of recovery. Except for a local increase of crepitant râles, there were no clear changes in the physical signs in the lungs during these focal reactions. Cough, however, was generally increased and sputum was at first more abundant if the patient had strength for expectoration. Subsequently both cough and sputum tended to lessen.

Headache was never intense. A general state of depression and lack of vitality together with loss of weight tended to develop in cases of extensive infection after a course of treatment, and this retarded subsequent recovery in the hospital wards.

Effects of the Injection of the Protective Serum.

Clinical experience varied on this point. At some hospitals nearly every patient had severe serum sickness, perhaps with its own rash and vomiting, and certainly with severe joint and muscle pains. Other observers never saw such effects. The differences were not explained by reference to any particular batch of serum, or to different effect of calf or of horse serum respectively. There were, however, no examples of dangerous anaphylactic phenomena.

It was difficult to form a clear conclusion as to the benefit of the serum. Some observers thought they had proof of its power to control albuminuria and focal reactions in the lungs, if given early and before these features became serious; others were not convinced. In general, serum was freely used for severe cases of infection. A few trials were made of the influence of the serum on the general state of a tuberculous patient apart from the use of sanocrysin, but they led to no demonstrable results.

Summary of Clinical Results.

Clinical experience in Britain has confirmed the description in Prof. Möllgaard's book of the immediate effects of sanocrysin as seen in Danish hospitals. The drug does appear clinically to have a specific action on tissues infected by tubercle bacilli, and the severity of the constitutional reactions does appear to be directly related to the intensity of the tuberculous infection. Further, the drug seems to have but slight toxicity for human patients who are not infected by tuberculosis, though in this respect very few control observations have been made. On account of the severity of the reactions in the first tuberculous patients chosen for treatment, no observer at the beginning felt justified in deliberately making control observations in other febrile infections. For the same reason no one cared to begin straight away with the treatment on a large number of tuberculous cases, but each observer preferred to select three or four individual patients and proceed cautiously.

The total number of cases covered by this preliminary report is small, about 30, of whom 22 definitely had tuberculous infections of the lungs. Two of the pulmonary cases died, death in one hopeless case being perhaps accelerated by the treatment, and occurring in the other unexpectedly as the result of toxic jaundice. The remaining 20 do not lend themselves to any numerical analysis. Uncomplicated pulmonary tuberculosis is a disease of which few physicians can confidently foretell the progress, upward or downward, during any given period of two or three months, which was all the time available for these preliminary observations. But it was the opinion of those observers who had had most experience in dealing with consumption that the early cases of open tuberculous infection of the lungs did show some evident improvement, though there was no dramatic benefit, such as that seen with insulin or salvarsan in their corresponding diseases. On the other hand, cases with more advanced disease did not stand the treatment well, and the condition of some of these has been made worse. The latter experience accords with that of Dr. Secker of Copenhagen. Serious cases of long standing cannot endure the treatment in its present form.

There were two cases, not included in the preceding 20, in which most striking improvement followed at once upon the use of the drug, both the patients having lain three months in hospital previously without making any advance. One appeared to be a case of closed tuberculosis of the lung, spreading out from hilum glands, though it could not be proved that the pulmonary inflammation was caused by tubercle bacilli and not by some other smouldering infection. The other was a case of tuberculous peritonitis with an encysted collection of fluid that vanished at once upon treatment. In each instance the patient showed the rash and rise of temperature that in other proved cases of tuberculosis have followed the injection of sanocrysin. No case of pleural effusion was treated in this preliminary group because the results in this condition would not have offered any decisive evidence. Lupus of the skin, spinal caries, renal tuberculosis, and tuberculous glands are now being treated; but their progress is not sufficiently advanced to be included in this report.

The evidence, therefore, despite the relatively poor results in open pulmonary tuberculosis, and that is unhappily the commonest form of tuberculosis, is sufficiently encouraging to demand further clinical study. This is particularly so in view of the one experience common to all observers—namely, that the drug seems to exert a specific action on tuberculous tissues. The Medical Research Council expect that many months will pass after the issue of this preliminary report before any further definite conclusions can be drawn. Trial on a larger scale is now justified, and it is hoped to widen the field of work with the help of more observers. But the Council are of opinion that such further trial and extended observations are imperatively required before it can be clearly stated that this gold salt is of value in the treatment of tuberculosis and before it should be made available for general use in medical practice in Great Britain.

II. CLINICAL OBSERVATIONS.

The following section briefly resumes the clinical observations at the several places where the treatment was used. In every patient radiograms of the chest were taken before, during, and after treatment.

St. Bartholomew's Hospital (Prof. F. R. Fraser).—One case, 30 years old, general pulmonary tuberculosis; T.B. found once. Total gold salt used, 5·25 g. Severe reaction at first, but final injection of 1 g. caused no rise of temperature. No definite change.

London Hospital (Prof. A. W. M. Ellis).—Five cases of pulmonary tuberculosis, one case of tuberculous meningitis, and one non-tuberculous control. The general impression of the results was definitely unfavourable.

CASE 1.—Aged 17. Four years' history extensive pulmonary tuberculosis both lungs. General condition good; had gained 1 st. in weight. Tubercle bacilli found once during treatment. Total gold salt used 6·5 g. in eight weeks. Severe reactions, fever, rash, ophthalmic reactions, albuminuria, loss of weight. Gradual recovery on stopping treatment to conditions very much as on admission. No change in physical signs. Result: No change.

CASE 2.—Aged 53. Three months' history of pleural effusion and fibrosis. General condition fair. Tubercle bacilli present on one occasion only. Total gold salt used 2·75 g. Gold salt discontinued because of prostration, albuminuria, prolonged nausea, and anorexia. Severe serum sickness. Lost weight and has not regained it two months after cessation of treatment. Result: No improvement, apparently made worse by treatment.

CASE 3.—Aged 23. Two years' history. Extensive pulmonary tuberculosis both lungs. General condition good; had recently gained 1 st. in weight. Tubercle bacilli disappeared from the sputum during treatment but reappeared later in large numbers. Total gold salt used 1·5 g. Gold salt discontinued because of vomiting and continuous hiccough. Prolonged anorexia. Fever, rash, and albuminuria. Three weeks after last injection onset of hectic temperature with physical signs indicating rapid and extensive spread in the area of pulmonary involvement. No subsequent improvement. Is going steadily downhill. Result: Treatment led to extensive spread of the disease and marked general deterioration.

CASE 4.—Aged 36. Three years' history. Extensive chronic tuberculosis both lungs. General condition excellent, afebrile; albuminuria. Renal function normal. Tubercle bacilli absent. Total gold salt used 5·5 g. Moderately severe febrile reactions, nausea, and vomiting. Ten days after the last injection temperature became hectic and has remained so with marked increase in physical signs and evidence of rapid spread of the infection. At the same time there appeared a very severe exfoliative dermatitis apparently identical with that seen in severe arsenical poisoning. Result: Extensive spread of the disease. Severe exfoliative dermatitis.

CASE 5.—Aged 19. Three years' history. Extensive chronic pulmonary tuberculosis of left lung, early involvement of right. General condition excellent, afebrile. Tubercle bacilli disappeared during early part of treatment but reappeared later in increasing numbers. Total gold salt used 7·5 g. Treatment followed by severe and prolonged reactions with fever, rash, albuminuria, and breathlessness. Severe serum sickness. After the third injection the temperature never again reached normal, the physical signs in the chest increased both in quantity and in extent, and tubercle bacilli reappeared in the sputum. Subsequent injections failed to influence the course of the disease. Serum, when given, resulted in violent reactions with rigors and collapse. The resulting situation was a very difficult one. It was obvious that the patient was going steadily downhill. It was decided to try and increase the concentration of the drug even though, on account of the reactions, serum could not be given. Two injections of 1·0 g. were therefore given with one day intervening. Four hours after the second injection there were dyspnœa, cyanosis, and blood-stained frothy sputum. Death occurred in two hours. There was no post-mortem examination. Result: Death.

CASE 6.—Aged 9 months. Tuberculous meningitis. Total gold salt used 0·4 g. in two days. No evidence of any effect was seen. Death occurred on third day. Result: No influence detected.

CASE 7. *Control.*—In addition a case of lymphadenoma or Hodgkin's disease was treated as a control. The patient received three injections of the gold salt and no serum. There was no rise of temperature, no albuminuria, and no rash, but nausea and prolonged anorexia resulted.

St. Mary's Hospital (Prof. F. Langmead).—Three cases of pulmonary tuberculosis. The early results were unfavourable and one patient died, apparently in consequence of the treatment.

CASE 8.—Aged 18. General condition good, but T.B. abundant. Total gold salt 1·5 g. in four days and over 200 c.cm. serum. Vomiting, diarrhœa, rash, fever, albuminuria, and definite serum reaction. Focal reaction in lungs. On tenth day after the last injection of gold salt jaundice appeared and rapidly deepened. The patient died with hæmorrhage from the bowels 29 days after the last injection. Necropsy found spreading tuberculosis in the lungs and recent tuberculous ulceration of the bowels. There was only one hypertrophied kidney and that showed tubular nephritis. The kidney was not analysed for gold, but in the liver was found 0·028 g. of gold—i.e., 4·75 per cent. of the total metal injected.

CASE 9.—Aged 32. Early disease of right apex, afebrile. T.B. present. Total gold salt 5 g. Fever, rash, loss of weight, albuminuria; general condition deteriorated, but is now improving and temperature is again normal. Physical signs unchanged and T.B. still present in sputum.

CASE 10.—Aged 29. Peribronchial fibrosis and doubtful physical signs, but T.B. present; temperature normal. Total gold salt 6 g. Fever, severe serum sickness, loss of weight, slight albuminuria, pain in chest, and increased expectoration. General condition at first worse but later improving. No T.B. in sputum in last three weekly examinations, but patient developed pleurisy seven weeks after treatment was ended.

St. Thomas's Hospital (Prof. H. MacLean).—Only early or slight pulmonary tuberculosis was treated, in five cases of which four had T.B. present. They were in fairly good general health, with few symptoms and generally very little pyrexia. Gold salt was given in doses of 1 g. at four to seven days' interval up to a total of 4 or 5 g. No serum was used. The reactions were slight, a little pyrexia, some albuminuria, and increase of cough. No focal pain in the chest, no anorexia. All the five cases have subsequently improved, but it is difficult to decide whether this improvement is more than would have been effected by ordinary hospital treatment. This group is, however, of great importance as a control to show that the gold salt exerts little obvious effect on the general health of patients with only mild tuberculous infections.

Case 11.—Aged 27. Three months' history. No T.B. 4·5 g. given. No reactions except slight albuminuria persisting since fourth dose. General condition improved. X ray: Disappearance of triangular opacity in right axilla which had suggested tuberculous infiltration.

Case 12.—Aged 21. Six months' history. T.B. present. X ray: Disease upper third both lungs. Very dense R. apex, moderately dense L. Some fibrotic contraction R. apex. Had begun to improve already with hospital treatment. 4·25 g. given. Slight temperature reactions. Transient albuminuria for five days after fourth dose. Result: Previous rate of improvement maintained or accelerated. Final radiogram shows no change except increased contraction R. apex, though radiogram taken during reaction showed increase of shadows. T.B. present on discharge but some evidence of fragmentation

Case 13.—Aged 28. Three months' history T.B. present. X ray changes of medium density both lungs, occupying one-third of pulmonary fields. 5·25 g. given. No definite reactions. Irregular pyrexia persisted. Attack of pleurisy after four weeks. Result: General condition improved. X ray: No change.

Case 14.—Aged 18. Short history. T.B. present. X ray: Medium opacity upper half both lungs. General condition good. 5·25 g. given. No marked reactions. Result: General condition improved. Sputum: No T.B. on March 9th, 1925. No sputum since.

Case 15.—Aged 24. Eighteen months' history. T.B. present. X ray: Very slight changes L. apex. General condition not very good. Two doses, each followed by slight pyrexia. Rash resembling erythema multiforme two days after second injection. Increased slowly during next six days. Began to fade on fifteenth day. Treatment in consequence delayed, and is now being completed.

University College Hospital (Prof. T. R. Elliott).—Four cases, of which two appeared to be cured by the treatment though the evidence was not conclusive. In two pulmonary cases with T.B. in the sputum the results were, on the other hand, definitely unfavourable.

Case 16.—Aged 18, bi-lateral apical infection with one year's history. Poor condition though afebrile and T.B. always in sputum. Total gold salt, 6·25 g. in 34 days, with 360 c.cm. serum. Much albuminuria, no rash, no severe serum sickness. Marked focal reaction in lungs, with pain, dyspnœa, and twice a serious circulatory collapse. Prolonged vomiting and anorexia. General condition worse and T.B. in sputum more abundant.

Case 17.—Aged 29, a hopelessly rapid caseous tuberculosis, chiefly of right lung, with less than six months' history. T.B. in sputum. Patient so ill that he seemed unlikely to survive more than a couple of months. Total gold salt, 4 g. in 11 days, with 300 c.cm. serum. Slight albuminuria and no rash. Marked focal reaction in lungs with dyspnœa that persisted. Died four weeks after last gold injection with repeated pulmonary oozings of blood. Necropsy confirmed the radiograms in showing that the caseous changes had spread rapidly into the left lung since treatment began, and the detachment of one large mass of caseous lung tissue loose within a cavity on the right side suggested that some unusually active process of destruction had been taking place. There was no tuberculosis outside of the lungs. Analysis found that of the total metallic gold given (40 per cent. of 4 g. salt—i.e., 1·60 g.), 0·128 g., or 8 per cent., was still present in the kidneys. The percentage of gold to the weight of the kidney was 0·037 per cent. The liver retained a total of 0·012 g.—i.e., barely one-seventieth of the percentage found in the kidney. The lungs contained only traces that could not be measured. This rapid disappearance of the gold from the tissues where its effect was desired suggests that the salt should not be given intensively in severe cases, as advised by the Danish physicians, but at longer-spaced intervals.

Case 18.—Aged 20, tuberculous peritonitis with large encysted collection of fluid in the lower abdomen. Pleurisy at 14, with present X ray evidence of fibrosis on right side. No T.B. in sputum and abdomen not explored. Condition stationary during three months' rest in hospital previous to treatment. Total gold salt, 4·5 g. in 17 days and 80 c.cm. serum. Febrile reaction, with rash and some pain in right chest and in abdomen. The tumour had vanished by the time that the last dose was given. No recurrence a month later, but still some chronic inflammation found on rectal palpation of the uterine adnexa. Patient gaining weight. Apparently a most definite improvement as the immediate result of treatment.

Case 19.—Aged 14, query localised tuberculous bronchopneumonia. Admitted for large quiescent tuberculous glands in neck, which were excised and microscoped. After anæsthetic for this operation patient developed consolidation of left lower lobe, which took four weeks to clear up. X rays subsequently showed much enlargement of hilum glands and a shadow spreading outwards in the middle of the right lower lobe. The patient was under medical treatment in hospital for three months, during which time there were no T.B. in sputum but there was continuous pyrexia and varying loss of weight. Boy seemed seriously ill when gold treatment was begun. Weight 5 st. 7 lb. Total gold, 1·25 g. in six days. Severe and prolonged rash, rise of temperature, and fall of weight to 5 st. 2 lb. No focal reaction in glands of neck. Then recovery, with temperature thenceforward normal and rise of weight by 2 or 3 lb. weekly to 6 st. 5 lb. on discharge from hospital. Still faint X ray evidence of fibrosis in area of earlier opaqueness in right lung. The boy was cured with unusual rapidity of his lung inflammation, which was not actually proved to be tuberculous, though its appearance was clinically identical with that of hilum tuberculosis.

Cardiff (Prof. S. L. Cummins).—Three cases of early pulmonary tuberculosis of which two showed definite improvement and one, whose preliminary course of treatment has only just been completed, feels better although he has not yet started to regain weight.

Case 20.—Aged 21. Early disease involving two lobes, but only slight in density. Fair general condition. T.B. present. Total gold salt, 4·5 g. in five weeks, 92 c.cm. horse serum. Moderate reactions after first four doses. Sputum ceased. T.B. vanished. Lost 2½ lb. during treatment. Has now regained this and added about 4 lb. to original weight.

Case 21.—Aged 28. Definite pulmonary disease right apex, with cavitation. T.B. present in great abundance. Total gold salt, 6·5 g. in seven weeks. 95 c.cm. horse serum. Moderate reactions and transient albuminuria after gold salt. Severe reactions after serum. Sputum diminished and T.B. greatly reduced in number. Has lost 9 lb. during treatment. Is now feeling "as he used to before illness," but has not yet started to regain weight.

Case 22.—Aged 15. Dullness and bronchial breathing upper third right lung. T.B. present in fair numbers. Good general condition. Total gold salt, 3·25 g. in five weeks. 36 c.cm. serum. Reaction and slight albuminuria after first dose. Intense serum sickness. Lost 3 lb. at first. Has now put on 4 lb. Is still under treatment. Appears much improved so far. No T.B. in sputum on last three examinations.

Edinburgh (Prof. Sir Robert Philip and Prof. D. Murray Lyon).—Work at Edinburgh was not commenced until January, and while a much larger series of cases was tried than at any individual centre in London few of these have yet reached the end of treatment. In general the results seem favourable. Serum was sparingly used, and in many cases not at all. In some tuberculous cases the Danish anti-tuberculin serum was used alone without the gold salt, and it was not seen to have any constant influence on the temperature curve. All the patients selected were without exception afebrile at the beginning of the treatment. In the pulmonary cases tubercle bacilli were present at the commencement. The first dose of ½ g. sanocrysin produced either very little reaction or a rise of about 2° F., the whole disturbance as a rule passing off in 24 to 48 hours. In two cases the temperature reaction to the first dose was prolonged for about ten days, a swinging temperature increasing for the first three or four days, reaching to about 103° F. and then gradually disappearing. No albuminuria or rash followed the first dose. The second dose of sanocrysin was usually followed by much larger temperature disturbance lasting a little longer than that of the half dose, but in most cases each subsequent dose gave rise to a smaller temperature response, until in some cases no rise occurred at all.

A large number of the cases complained of loss of appetite and in some the anorexia was very severe; vomiting has been frequent—in some cases within a few minutes after each dose, in other cases a few hours later; or again, occurring only in the early morning each day. A considerable quantity of albuminuria might appear after the second or third dose and remain present for several days, gradually decreasing in quantity, even without the use of serum. Renal cells and casts were present in some of the cases, but there have been no other signs of renal irritation or nephritis. A case of tuberculous kidney showed no increase in albuminuria under treatment, but after four doses treatment had to be suspended because of recurring vomiting. Skin rashes have appeared in about three-quarters of the cases, irrespective of whether they have had serum or not. The rashes have varied considerably in character, from fleeting erythemas and urticarias to persistent dermatitis. In some cases the whole rash disappeared in a few hours, and in many it lasted for three or four days. The rashes were judged by an observer who had clinical familiarity with those caused by extensive tuberculin treatment to be very similar to the latter. In one pulmonary case a severe reaction has persisted for about three weeks, the whole skin being inflamed, the tissues about the face swollen, and there has been a universal desquamation. Apparently this subject had had some previous skin trouble.

In three pulmonary cases with abundant T.B. and definite X ray changes there was some improvement. Sputum was lessened, but a severe rash occurred in two, and in one of these there was persistent vomiting and anorexia. In eight other cases, including lupus of the face, renal tuberculosis, and scrofulous glands of the neck, no alarming features of reaction have yet been observed.

THE HEALTH OF THE ARMY IN 1922.

THE report on the health of the army for 1922 [1] opens with a letter from the Director-General, Sir W. Leishman, to the Under Secretary of State for War, announcing improvement "in almost every direction" in the health of the army, which has, he adds, continued into 1923. The report for 1923 is already in preparation, for it is hoped that these reports will soon be issued within 12 or 14 months of the close of the period concerned. This is obviously a desirable change, since the sooner the reports appear after the events they summarise, the more useful they are to the officers of the army and the other services. This report is arranged in the same sections as last year.

General Considerations.

The physique of the army generally has improved, though standards are still lower than before the war. The average strength of officers in the regular army was 12,058, of whom 120 per 1000 were treated as out-patients, 298·3 were admitted to hospital (374·2 in 1921), and 4·48, against 5·9 in 1921, died. The chief causes of illness were diseases of the digestive system, other than of the tonsils or of the liver, 44·8 per 1000, and local injuries 44·1 per 1000. No "wounds in action" are mentioned, though three officers died in Ireland from gunshot wounds, classed as local injuries, and no suicide, though one is noted on p. 44. The number of officer invalids is not stated.

The average strength of warrant officers, non-commissioned officers, and men was 208,079. The ratio per 1000 of hospital admissions was 515·8 (650),[2] with deaths stated as 3·22, but really 3·38, when suicides are included (4·20; 4·32 in 1921), and invalids finally discharged were 19·31 (27·48); 31·54 (41·20) were constantly sick. Each rate is thus about 20 per cent. lower in 1922. The diseases causing the most numerous admissions to hospital were malaria 65·0 (99·8), "diseases of the digestive system other than those of the liver or inflammations of tonsils" 47·4 (58·6), gonorrhœa 46·8 (45·9), and local injuries, with 12 deaths in Ireland due to gunshot wounds, 45·0 (53·2). Influenza 29·6 (20·9) has slightly increased, sand-fly fever 18·8 (34·0) is much lower, and enteric fever 1·2 (1·5) is less. The most frequent causes of death were local injuries, 0·56 (0·78), pneumonia, 0·44 (0·52), general injuries, 0·29 (0·56), and "other diseases of the digestive system," 0·27 (as in 1921). Malarial deaths have dropped to 0·16 (0·27), tuberculosis, pulmonary, remains 0·18. The case-mortality of enteric fever was 11·6 per cent. (8·33), of pneumonia 10·57 per cent. (11·7), and of small-pox 27 per cent. (22); of the three reported cases of meningococcus infection two died. Troops on board ship numbered 4157, with admissions to hospital 364·0 (414·6); there were no deaths from pneumonia (0·44 in 1921).

The wives of other ranks, 16,811, were admitted to hospital, 47·9 (50·3) for disorders of the generative system, and "other diseases of the digestive system" came next, 23·7 (33·3). Their death-rate was 3·15 (3·74). They got enteric fever as often as the men, and died equally, but their admission for pneumonia and bronchitis were a quarter of the men's, and their death-rates a half. There were 26,080 children, with a death-rate of 9·59 (12·07), due chiefly to disorders of digestion, 2·65 (4·25). Mention is made of 2400 cases of parturition without any details; a statement of the results among this group would be interesting to the civil profession.

The medical specialist at Netley reports that disordered action of the heart (tachycardia) has no satisfactory treatment. He considers the strain of the service does not cause it, "as the young soldier leads a much more healthy life than he did before enlistment." But, we would point out, he also leads a much more strenuous life; and a report on the incidence of such cases in the large depôts might be useful (p. 33), particularly if one depôt were distinctly better fed than another; the provision of more rest and different food might have a bearing on the subject. A new diet, "scientifically balanced," was introduced abroad on Jan. 1st, 1922, but is not detailed in this report. The food of the boys of the army, at Woolwich, Chatham, and the Duke of York's School, was under consideration this year, and their diets were readjusted and improved. Venereal diseases are less frequent, especially at home. This is ascribed to better accommodation in barracks, also to the spread of temperance, to provision of preventive outfits (improved this year), and to better facilities for disinfection. Incidence in the army was 70·7 (74·0), but among the large commands, heaviest on the Rhine, 254·2. Cases of venereal disease are now treated in ordinary military hospitals, in special wards.

Medical Examination of Recruits.

The statistics are for the recruiting year, Oct. 1st, 1921, to Sept. 30th, 1922, in which 45,932 recruits were taken into the army; 40,934 born in England, 5704 in Scotland, 2013 in Ireland, and 308 elsewhere; 31,566 were rejected, either at once or within six months. The rejections, 407·31, were more numerous than in the previous year (382·81), the chief causes being sub-standard chest measurements, defective vision, ear disease, defective teeth, valvular and other diseases of the heart, flat-foot and other defects of the lower extremity. The rejections were, in this year, fewer for tubercle, defective intelligence, and diseases of the heart. The standards of chest, weight, and height which were accepted are not stated.

Hygiene.

Under this heading it is shown that, among the larger commands, venereal disease, digestive disease, and scabies were at a maximum on the Rhine, malaria in India, local injuries, diseases of the areolar tissue and tonsillitis in Egypt and Palestine, influenza in the United Kingdom, and sand-fly fever in Iraq. Malaria is being energetically and successfully controlled. The percentage of admissions to hospital was 65·0 (99·8), of deaths 0·16 (0·27), and of invalids finally discharged 0·17 (0·48). In West Africa 142 cases arose among 244 men; apparently at first no anophelines were found in barracks, but later it is said they were found in some, and that 7 per cent. were found to be infected. Palestine had less malaria; General Headquarters remained non-malarial, and there were no primary cases of malaria among the troops in Jerusalem. In Cyprus care was taken not to bring the troops into dangerous areas at bad seasons, but a refugee camp of heavily infected Russians spread malaria to troops near by. Gibraltar suffers through mosquitoes coming from Spain.

---

[1] Vol. lviii., pp. iv. + 100. H.M. Stationery Office. 3*s.*

[2] The figures in parentheses represent corresponding number for 1921.

The incidence of diseases of the digestive system was 47·4 (58·6) for men and for officers 44·8 (56·6). The improvement is ascribed to improved rations, better cooking and serving of meals, and oral hygiene. We may note that men suffer twice as much as officers from tonsillitis.

Influenza occurred chiefly at home. An outbreak at Redford, near Edinburgh, is believed to have been aborted by obligatory gargling and insufflation with 1/5000 potassium permanganate in normal saline, the affected barracks being put out of bounds to other troops, and double cubic space given to the men. Elsewhere early isolation, disinfection of drinking cups, and inoculation were also thought useful.

In West Africa an orderly with first-aid equipment attends at all football matches to minimise loss of service to the Crown from local injuries. Mother and child welfare schemes (entirely voluntary) are proving most valuable.

The Hygiene Department of the Royal Army Medical College passed 60 senior officers through courses and 9 for the specialist certificate, as well as 37 laboratory attendants. The museum is being rearranged and improved. Many investigations were made and some reports thereon published in the *Journal of the Royal Army Medical Corps.* The Army School of Hygiene at Aldershot absorbed the school from Blackpool and the Entomological Laboratory from Sandwich. It trained 5 officers and 48 other ranks, R.A.M.C. Two men were specially trained for the sanitary inspectors' certificate. Researches were conducted on water sterilisation, and on the life-history of *A. maculipennis.* The Army Hygiene Advisory Committee dealt with the energy expenditure of the soldier in training, the soldier's load,[3] and the application of motion study to digging, and visited barracks to decide important questions of sanitation. A War Office committee investigated problems of disinfestation, disinfection, and personal cleanliness on active service.

Pathology.

The staff of this section was rearranged. Pathology and hygiene were administered in small commands by the same officer; also the directorate of pathology took over the administration of venereal disease with its associated laboratory work, and all medical problems relating to chemical warfare. At the Royal Army Medical College 60 officers were trained in general and tropical pathology, 6 as specialists, and 36 men as laboratory attendants. Progress was made in the quest of a vaccine to prevent bacillary dysentery, and other vaccines, sera, and biological reagents were prepared and supplied to the Service, saving £16,000 to the public, which was also saved expense by the inoculation, at the College, of various Colonial and Indian officials. Various notes appear here on the work proceeding at present; the Sigma reaction is being found reliable; the type of pneumococci infecting a case is now quickly recognised, in the cerebro-spinal fluid, by the precipitin test; a new antiseptic ointment for the prevention of venereal disease has been devised and issued. The increase in venereal disease in the Rhine Army received much consideration. In Malta 14 cases of Mediterranean fever were recognised, 13 in native Maltese, who are not under the same sanitary control as the British troops. In Turkey fresh cases of dysentery were always bacillary and mostly of Flexner type; Shiga infections were infrequent but extremely severe; gonorrhœa cases got benefit from autogenous, but not from stock vaccines; nine cases of enteric fever were seen; blood cultures were obtained in nearly every case from the mercantile marine, but were little successful if patients had been protectively inoculated; a small outbreak of diphtheria in a British man-of-war was controlled by the laboratory; two cases of anthrax were cured with anti-anthrax serum. The R.A.F. seem to have taken over the pathological work of Iraq, except antirabic treatment, handed over to the civil authorities. We regret to notice that the laboratory at Khartoum had to be closed. Of 462 primary malaria cases examined there, 292 were benign tertian, 157 malignant tertian, and 13 quartan.

Dental Treatment.

New dental history cards have facilitated treatment by saving time spent formerly in repeated inspections. In 1922 the army had in it 208,079 men, of whom 158,793 were inspected by dental officers; 74·23 per cent. were selected for treatment, of whom 55·68 per cent., one-third of the inspected, had treatment completed during the year. The proportion of teeth saved goes on rising. Further, not half as many artificial dentures were required in 1922 as in 1921. In addition scaling and treatment for inflammatory conditions of the mouth were also done. Reports from abroad show that men sent from home require less dental treatment than in former years. India is absent from the dental returns and remarks both in 1921 and 1922, yet we observe that India has rates just below the average for diseases of the mouth and teeth and for diseases of the digestive system. Dental treatment was completed in 1922 for 1481 wives and children of soldiers.

Command Reports.

We have noticed in the reports from the larger commands that influenza was most prevalent at home, 46·2, especially at Aldershot, 65·3, but Aldershot had the fewest cases of tubercle, pneumonia, and bronchitis; Ireland had, as last year, a low rate. The Northern Command, 7755 men, had the highest rates and the Rhine was hardly higher. The death-rate on the Rhine was 6·29, the highest in any large area, while its venereal rate, 254·2, was enormous (army generally, 70·7), yet the proportion of bachelors in that army was a minimum. This Rhine area evidently requires careful watching. Its rates for diseases of the teeth and for diseases of the digestive system are a maximum, and the women here, and the children, have death- and sickness-rates higher than those observed in the United Kingdom.

	Admission to hospital per 1000.		Death-rates per 1000.	
	U.K.	Rhine.	U.K.	Rhine.
W.O.'s, N.C.O.'s, and men.. ..	376·4	689·7	1·86	6·29
Women	75·3	106·3	2·39	3·57
Children	61·4	144·4	4·02	6·95

The report contains notes on the management of nocturnal incontinence in soldiers on p. 38, on mental cases on p. 50, and on the prevention of malaria on p. 60, to which we direct attention. The death-rate in India, 7·09 in 1921, has been reduced to 4·84, but as compared with that, 3·26, in 1913 is still too high.

There is still work to be done in the building up of a healthy army. This end has, however, been brought nearer by the campaign of the R.A.M.C. against disease, well planned in 1921, and beginning to bear good fruit in 1922, with a 20 per cent. reduction of the admissions to hospital and of the death-rate.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.[*]

(Continued from p. 786.)

EVIDENCE OF MINERS' SOCIETIES (*continued*).

Mr. E. Hibbert and Mr. D. Shaw gave evidence for the Lancashire and Cheshire Miners' Permanent Approved Society. (Q. 6969.) With regard to the suggestion made previously that segregation of membership under occupations was producing unfortunate results, the witnesses pointed out that there are normally about 1,100,000 persons engaged in the mining industry on the surface and underground; but in the miners' societies there are only 170,000 insured persons.

(Q. 6970.) Even with this so-called segregation we should do very much better if we had dental treatment. I am sorry to trouble you so much with dental treatment, but everything seems to turn on that.

Need of Dental Benefit: Evidence of Excessive Sickness for Lack of It.

(App. XI., 24.) This society urge that this should be a statutory normal benefit and that members should pay no part—or at any rate only a very small part—of the cost of any dental services necessary. They consider that this would transform their present unfavourable sickness experience. They had asked the regional medical officers to refer in their reports to the condition of the teeth of sick members referred to them for examination.

The regional medical officers have very kindly complied with this request. It is quite obvious from those reports—and they confirm our previous impressions formed as laymen of the position of this subject—that a considerable proportion of our excessive sickness experience is due to this preventable cause.

(Q. 6984.) The witnesses suggested that miners are more in need of dental treatment than any other class.

Supply of Appliances.

(App. XI., 22.) In addition to dental treatment, the witnesses considered that the supply of certain appliances—trusses, spectacles, knee-caps—should not be dependent on favourable valuation results, but should be supplied generally, subject to a condition that their provision should enable insured persons to resume work.

Higher Rates of Sickness Benefit.

(App. XI., 10.) This society would like to have the normal rates of sickness and disablement benefits increased for married men with a rising scale for those with children under 14.

(Q. 7016–51.) With regard to sickness experience generally, the witnesses contended that by paying out sickness benefit from the date of the doctor's certificate and not from the date of receipt of the claim, their society were paying out as much as 10 per cent. in excess of what other societies in most cases were paying. They admitted that the other societies were complying with the Act of Parliament and that they were not, but suggested that the Act of Parliament was at fault. The witnesses were taken to task for quoting special circumstances in support of their contention.

(Q. 7027.) You are quoting one sort of special incident after another. First of all you quote the man who lives seven miles from the colliery; then the man whose household consists of himself and his wife; and then the case of a wave of influenza passing over the whole village. What you tell us here is, that if you habitually, and as a matter of practice, carried out what appears to be the Act of Parliament you would save 10 per cent. of your sickness claims?—Yes.

Age at Entry.

(Q. 7060–3.) The suggestion in this evidence that persons should become insured at 14 instead of 16 was not pressed when it was pointed out that this would tend to stereotype the earlier age as one suitable for children to go to work. They pointed out, however (Q. 7119). that economic necessity induces miners to send their children to work at the earlier age. In any case the principal reason for the proposal (Q. 7063) was not to secure cash benefits but to get the advantage of medical treatment.

Insurance Committees Useless.

(App. XI., 27.) This society is uncomprising in its attitude towards Insurance Committees. It considers them useless and thinks they ought to be abolished.

Complete Pooling of Funds.

For the Lancashire and Cheshire Miners' Federation Approved Society, Mr. Lee Shaw gave evidence. The evidence in this case was almost entirely on the suggestion that there should be a complete pooling of funds.

(App. XII., 3.) Approved Societies consisting of miners only are almost without exception in the unfortunate position of not being able to provide additional benefits. The fact that a heavy sickness experience and invariably a high maternity-rate experience, in connexion with such societies, has prevented the accumulation of funds to provide additional benefits in itself suggests that the need is equally great for the provision of additional benefits, and possibly greater.

(Q. 7227–67.) This witness considered that with a complete system of pooling of funds, a close central control and the strong sense of duty of local administrators would be sufficient to prevent lax administration or loss of benefit funds.

(Q. 7245–6.) Would it really not mean in the long run—it might not happen at once—that Approved Societies as we know them now would disappear?—Exactly.—Q. I want to ask you whether from the general point of view you would regard the disappearance of Approved Societies as we know them without regret?—I do not know that I should. I think that every town looking after its own insured persons could do it effectively and could administer it with that sympathy which we feel is necessary in the case of sick persons.

(Q. 7382.) The witness advocated an increase in the present rates of sickness benefit.

Pithead Baths.

(Q. 7387.) Are you of opinion that it would tend to improve the health of miners generally if we had a system of pithead baths so that men could bathe themselves properly and change their clothes and go home comfortably attired in all sorts of weathers?—Yes, I hold very definite views. It would be a great advantage to the miners if we had pithead baths, and it would appreciably improve their health.

Mr. Lee Shaw said that pithead baths were established in connexion with the Atherton Collieries and that they were very much appreciated.

EVIDENCE OF MR. ALBAN GORDON.

(App. XIII.) Mr. Gordon is secretary of the United Women's Insurance Society, but gave his evidence as an individual.

Weakness of the Approved Society System.

(App. XIII., 5.) In Mr. Gordon's view, the administrative weakness of the Approved Society system lies, first, in the enormous number of Approved Societies (8427 separate administrative units) with their consequent overlapping and duplication of machinery, and in the small size and membership distribution of many of them. The system, he says, stands condemned for the following amongst other reasons: (9) the undesirable competition between the societies; (10) the overlapping and wasted effort; (12) the elaborate central machinery necessary to supervise them, and (14) the farcical nature of the so-called democratic machinery. (16) The vested interests in their own posts or in their organisations, says Mr. Gordon, coloured the views of society officials on the working of the National Health Insurance Acts.

---

[*] In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247–8); The Provision of Medical Benefit (Feb. 7th, pp. 301–3; Feb. 14th, pp. 355–6; Feb. 21st, pp. 403–5); Financial Provisions of the Act (Feb. 28th, pp. 454–7); Medical Certification and the Regional Medical Staff (March 7th, pp. 508–9); The Approved Societies and the Money Benefits (March 14th, pp. 564–5; March 21st, pp. 623–4); Evidence of the Hearts of Oak Society (March 28th, pp. 677–9); Evidence of the National Conference of Industrial Assurance Approved Societies and of the Manchester Unity Approved Society (April 4th, pp. 731–3); Evidence of Independent Order of Rechabites, of Rational Association Friendly Society, and of Miners' Societies (April 11th, pp. 784–6).

References to the printed statements issued as appendices to the reports of the oral evidence are given thus; Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

Political Dangers.

(App. XIII., 17.) As an illustration of the political dangers attaching to the present system, the witness referred to the bitter dispute between the societies and the medical profession in 1923 and to the setting up of an Emergency Committee of Societies to bring pressure to bear on Parliamentary candidates.

Of the 15 million insured persons,

> probably 14¾ million had not even the knowledge that the controversy was taking place, still less as to the true merits of it. The "Emergency Committee" had not the slightest vestige of claim to represent anybody, yet by virtue of the mock-democracy of the Approved Society system it wielded the political authority of 15 million persons, largely electors.

A Territorial Organisation.

(App. XIII., 20.) Mr. Gordon considers that the objections to the Approved Society system of administration could be met

> by regrouping Approved Societies on a territorial basis, and setting up one Approved Society for each county or county borough, or other local unit, with or without the possibility of local occupational societies where the number of persons engaged in the same occupation in any given locality was sufficiently numerous for a special society to be set up for the employees in that industry in the locality should they so desire.

(App. XIII., 21.) Although he thinks that the continued existence of Insurance Committees with their present limitations is, except for the functions performed by the Medical Service Subcommittee, a pure farce, Mr. Gordon considers that

> these bodies, being on a territorial basis, command a great deal of public-spirited service which could well be utilised to better purpose, and the suggestion comes naturally to mind that the machinery of Insurance Committees might form the basis of a new type of Approved Society.

(Q. 7798.) As to the Medical Service Subcommittees, Mr. Gordon said that they very often work in an erratic and capricious fashion but that the system is right.

(Q. 7452.) The witness's plan is to take "suitable local areas"—and in this connexion it is to be borne in mind that a Royal Commission on Local Government areas is now sitting—and have an Approved Society for each area administering cash benefits, and a co-terminous organisation, a Health Council, administering medical benefit and in fact all local medical and sanitary services.

What is to Happen to the Old Friendly Societies.

(Q. 7581.) The present work of the old Friendly Societies in the provision of cash payments during sickness is, says Mr. Gordon, obsolescent. They led the way for many years, but the State has now caught them up.

> The old work of Friendly Societies seems to me to be done, and it is not for them now to try and stand in the way and say: "This is our sphere, and nothing else must be done in this sphere." I think it is for the Friendly Society vanguard, having been caught up by the main army now, to move on into other spheres.

(Q. 7505.) Though describing himself as a very strong lover of Friendly Societies, Mr. Gordon said that he felt that

> what is popularly called the Friendly Society spirit to-day is growing to be a definite hindrance in National Insurance administration and definitely contrary to the good both of Friendly Societies and of National Social Insurance.

Grave Defects of Medical Benefit.

(App. XIII., 31–48.) Mr. Gordon would take medical benefit altogether out of the Insurance Act; he suggests that it is a misuse of terms to call it part of an "insurance scheme" in view of the fact that scarcely any element of uncertainty enters into its financial side.

> The grave defects of medical benefit—so grave as almost to merit the description tragic—are: (1) the narrow limits assigned to the range of services to be rendered as medical benefit; and (2) the entire absence of any coördination between medical benefit and other branches of medical or public health services.

In addition, the present system possesses the considerable fault of being unduly expensive. The part-time basis of remunerating practitioners is "extremely wasteful." The capitation fee had been unduly inflated because

> in calculating the remuneration of panel practitioners regard had to be taken of the establishment and overhead charges of as many surgeries as there were practitioners. Every separate doctor, or partnership of doctors, maintains his separate waiting room or rooms, often crowded, inconvenient, and even insanitary, his own consulting-room, his own filing and clerical system, his own means of transport.

A National Medical Service.

(App. XIII., 42.) This witness would have a comprehensive national scheme of medical services. Although personally in favour of a salaried organisation, he thought a capitation system of payment a possible though a more costly and less efficient method. He commended to the notice of the Commission the scheme drawn up by Lord Dawson's Committee (Cmd. 693, 1920) and, as regards hospitals, the Labour Party Caxton Hall resolutions of April, 1924. He thought it clear

> that the policy of these resolutions could be so developed that the hospital services of the country could be augmented, improved, and brought into close relationship with a National Medical Service without derogation of the magnificent amount of voluntary work that for many years has been such an admirable feature of British hospitals.

Free Choice of Doctor a Superstition.

(Q. 7842.) Would you retain free choice of doctor for the patient?—In the face of circumstances, yes, although I cannot help regarding that as a survival of the superstitious side of medicine.

(Q. 7858.) Both from the point of view of the patient and from the point of view of the doctor it is highly desirable that the patient should have free choice?—I agree in the present state of public opinion, but I do not agree intrinsically.

Team-Work amongst Doctors.

(App. XIII., 40 and Q. 7870.) Mr. Gordon suggested that, apart from statutory reforms, it would be a great step forward if general practitioners could be linked up together in groups, so that instead of every man providing his own waiting-room, consulting-room, &c., groups of doctors might work in well-designed and well-equipped suites of waiting- and consulting-rooms, with properly qualified attendants, nurses, clerical assistants, &c. This would permit of some degree of specialisation and it would facilitate holidays, periods of study, &c., among the doctors concerned, while the patients would receive quicker and more effective attention. Such a reform must develop amongst the doctors themselves but might be "gently assisted" from without.

KING EDWARD VII. SANATORIUM, MIDHURST.—From the eighteenth annual report dealing with the period July, 1923, to July, 1924, it will be seen that 294 patients were admitted to the sanatorium, including 20 readmissions and 19 who remained in residence too short a time to be considered in the records. During the same period 234 patients were discharged, of whom 65 were placed in Group 1 (disease of slight severity limited to small areas of one lobe on either side), 44 in Group 2 (diseases of slight severity, more extensive than Group 1, but affecting at most the whole of one lobe), and 125 in Group 3 (all cases of greater severity than Group 2). A steady demand for beds is recorded, the average number of patients on the waiting-list per week having been, for men 6·3 and for women 6·7.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.

POST-GRADUATE EDUCATION.

THE resumed discussion[1] on this subject took place on April 8th, Sir Arbuthnot Lane, President of the Fellowship, being in the chair.

Sir Thomas Horder said that the discussion had already shown a general agreement as to the need for post-graduate teaching and the desirability of extending the present activities of the Fellowship. The post-graduate habit in this country needed stimulating and it was from within the profession that that stimulus should come. Four suggestions might be considered: (1) That the panel of those willing to assist in post-graduate work should be made smaller, containing only carefully selected names. (2) That the teaching staffs of undergraduate schools should be recaptured for this work. The speaker was sure that they would be willing to assist. (3) That it was imperative for the Fellowship to find a home of its own, if only a room, some temporary fabric where tuition could be carried on. (4) That a hospital was essential. The Fellowship should never rest satisfied with any scheme which did not include a college for teaching and a hospital for practice.

Dr. W. Griffith said that it was unanimously admitted that any medical service to be adequate must keep up post-graduate work. The military and naval services made arrangements for this; the national health insurance service did not. He suggested that the Minister of Health should be approached with a view to some scheme whereby panel practitioners could be given periodical study-leave at the expense of the Ministry, and that one of the large general hospitals should be established as a centre of post-graduate study.

Dr. F. Hernaman-Johnson spoke of the genesis and work of the Radiological Institute. They had found that nothing could be done until a home had been obtained. It was hoped that the Institute with its X ray museum would be able to help with post-graduate work next autumn. He thought that there was a reciprocal duty on the part of the teachers and the Fellowship; the former should be there at the time appointed, while the latter should undertake to provide him with somebody to teach. Neither of these duties was always fulfilled.

Sir James Dundas-Grant described the work of the old Polyclinic, which had done such valuable service in providing daily demonstrations by members of hospital staffs followed by lectures, commencing at 5.15 and given by the same teachers or by members of consulting staffs, the nature of the demonstration being fixed for each day of the week. A nominal annual subscription entitled practitioners to attend these classes, and although no honorarium was offered plenty of distinguished men came forward to assist in the provision of them. He suggested that something on these lines might be started at once.

Mr. F. J. McCann said that the time had come when the Fellowship ought to be able to lead an independent existence. It needed money, a home, and a man. He suggested that an appeal should be launched from the Mansion House for £50,000; the public could be interested and made to realise that to contribute to better medical education was one of the best methods of life insurance. There should be a college and a hospital and the two should be linked by links of gold, the lecturers being well paid for their work. At the head of it should be one capable man to resolve conflicting interests and ensure harmonious working.

Mr. H. W. Carson spoke of the difficulty of getting the whole profession on the side of post-graduate education; the undergraduate teaching staffs did not so much need "recapturing" as interesting in the first place. Many foreigners coming to London were disappointed at finding that there was no way of seeing the work of certain world-renowned practitioners. The provision of a central hospital had many difficulties; it did not seem likely that any existing one would consent to devote itself to post-graduate work and to build one would be a colossal undertaking; the staff of such an institution must either be fixed, providing a very limited number of teachers or, if it were fluctuating, the hospital would be run with much difficulty and the turn of some people would be long in coming. On the other hand, a home and hostel was absolutely essential, with someone in charge of it. At the North-East London Post-Graduate College it had been found a successful plan to allow local practitioners to become members of the College for a small subscription. This enabled them to use the hospital when they liked. He suggested that the Fellowship should invite local hospital centres to receive members of teaching staffs for the purpose of conducting demonstrations.

Dr. Sophia Jevons said that she spoke as a student and was disappointed to hear no practical schemes put forward; all these suggestions were very idealistic, and demanded large sums of money and time for their development. The public were willing to subscribe for a cancer fund because they were terrified of getting cancer; they would never subscribe to a fund for medical education.

Dr. Bernard Myers said that what people who came to the classes wanted were cases they could examine themselves, chiefly common cases, with a few rare ones, clinical lectures and demonstrations giving detailed differential diagnosis, prognosis, and treatment with pathological specimens. They liked their teachers to be authorities on the particular subject under discussion. The American visitors had told him that they saw better cases in London than in any part of the world. A centre would be advantageous and Bloomsbury was the place for it; the hostel suggested by Sir Thomas Horder was very necessary and practical. General practitioners wanted to be able to attend classes at some local hospital where they were within telephone call of their work. He suggested that teachers might be sent out to cottage hospitals to take the work of the day in them. He was certain that if a reasonable sum were asked for it would be obtained.

Sir Henry Simson said that the Polyclinic failed because it provided too many lectures; the post-graduate student wanted to examine cases. There were four types of student: (1) The man who came to see the work of some particular individual. It should be possible for the Fellowship to give him a card of introduction and to communicate with that person on the telephone informing him of the arrival of the visitor. (2) The man who wanted demonstrations in special subjects. (3) The man who wanted three or four weeks' work in general medical knowledge. For him there were already four hospitals in London if he chose to attend them—the North-Eastern, the Royal Northern, the West London, and the Hampstead General. (4) The general practitioner who wanted classes on one day a week.

Prof. Louise McIlroy said that there was a great demand for and a grave lack of provision of obstetric teaching in London. Some special scheme was needed whereby a course in this subject could be arranged three or four times a year. More and more antenatal clinics were being established and the local practitioners were expected to be competent in this subject; it was possible that the Ministry of Health might support some arrangement for training medical officers for these centres.

Mr. E. B. Turner expressed his agreement with Sir Thomas Horder and Dr. Myers; in his opinion the immediate provision of a home and hostel were within the realm of practical politics; the latter might, indeed, be made a commercial speculation. Post-graduates wanted training in the technical management of cases requiring modern methods of treatment. The present hospitals providing post-graduate work were rather far from the centre. He wondered why more use was not made of the excellent material provided in the Poor-law institutions. Study-leave for panel practitioners was an excellent idea, but most panel practitioners were also engaged in private practice, and even if allowed leave from their panels might not find it easy to escape the multifarious calls of private work.

---

[1] THE LANCET, March 28th, p. 681.

A letter from an overseas post-graduate student was read by Dr. A. J. Whiting, criticising present arrangements on the grounds of the time wasted in getting across London, in the late attendance or failure to attend of appointed teachers, and the inability of some teachers to teach. He suggested that concentrated courses of a month's tuition consisting of six or seven hours a day for seven days a week should be provided to include the examination of selected out-patients, demonstrated by a first-class person, with an exposition of his own views and those of other eminent people as to all modern methods of differential diagnosis and treatment; attendance at operations in all branches, frequent demonstrations on the cadaver, constant revision of anatomy, &c. He would not want to hear lectures or see large collections of cases or to suffer long disquisitions on theory or the autobiography of the teacher. The young graduate should be separated from the man who had been specialising some time.

Mr. J. P. Lockhart-Mummery said the difficulty was a financial one. He had been treasurer of the old Polyclinic and they had always been held up by lack of funds. The post-graduate must put up what money was required himself; the public would not help. The material was all to hand, but unless 5000 practitioners could be found to subscribe £1 a year each towards organisation that material could not be properly utilised.

Dr. R. A. Gibbons agreed with Mr. Lockhart-Mummery, and thought that the profession might be appealed to for a moderate subscription.

Dr. C. M. Wilson said it was most important to find out what they were trying to do. In his experience the general practitioner would not come in large numbers for a period of two or three weeks, but he would come one day a week for special lectures if the man he wanted was there to lecture. The teaching technique was a most important factor; the formation of a new polyclinic would only solve the problem if the teachers were most carefully selected. In Berlin the arrangements were much more convenient as the best people were all concentrated at the University. A practical difficulty was that if the popular teacher gave demonstrations they would soon cease to be demonstrations because so many people would attend them.

Mr. H. J. Paterson said that the London Temperance Hospital had decided to give an experimental course of two weeks' tuition daily at 4.30, consisting of an hour's demonstration of cases followed by a short lecture, the subscription being one guinea.

BERLIN.

(FROM OUR OWN CORRESPONDENT.)

Heidelberg as a Spa.

THE ancient city of Heidelberg, renowned for its very old university, the ruins of its castle, and its picturesque site, has now added the attraction of a watering place. A spring has been found at a depth of 1000 metres, containing sodium chloride, carbonic acid, and radium, without the presence of sulphates. The spring will be useful to patients suffering from rheumatism, gout, neuralgia, sciatica, arterio-sclerosis, bronchitis, gastric and intestinal catarrh, rickets, and scrofula. The city authorities are anxious to make Heidelberg a first-class spa; the construction of a modern bathing establishment is proposed and other arrangments to secure an efficacious "cure" will be made. They hope that not only the spring and the attractions of the old city, but also the fact that the patients have during their stay the opportunity of consulting leading medical men who belong to the university, will bring a number of visitors.

Poisoning by Ginger-Bread.

Some cases of arsenical poisoning by ginger-bread have recently been observed in Breslau. It was ascertained that the potash which is usually added to the dough to make it softer contained arsenic. The potash had been extracted from the wool of sheep which had previously been treated with arsenic compounds. The Health Office has therefore instructed druggists and chemists to ascertain whether the potash for sale contains arsenic, in which case it is enacted, naturally, that it must not be sold for cooking purposes.

An Unusual Danger.

A doctor of Fürstenwalde, near Berlin, was lately consulted by a man who came, in the guise of a patient, accompanied by an attendant. The latter was supposed to be necessary because the patient alleged himself to have contracted an injury which prevented him from walking upright. He came, therefore, creeping, so that the medical man could not see his face. When the medical man bowed to examine him, the patient tried to strangle him by getting hold of his neck, whilst the companion tried to stab him. Notwithstanding his age, 63, the medical man was able to hold his own until his servant arrived. The assailants fled but were arrested by the police and were sentenced to four and six years' hard labour.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Pre-Natal Work in Paris.

Prof. A. Couvelaire, of the Baudelocque Hospital, in an account of the pre-natal work to which he has contributed much during the last few years, points out that it is insufficient, and often useless, to protect the child only from the moment of its birth. Insufficient because in France nearly 35,000 infants die annually within a few hours of birth, in the last few months of pregnancy, or during labour. Useless because out of the 70,000 to 80,000 infants who die annually in France before reaching the age of one year, more than one-third die because they have been born prematurely or suffer from some congenital disease. Of every 100,000 to 110,000 infants dying between the sixth month of pregnancy and the first year, over 50,000 suffer from pathological conditions existing prior to their birth or die from the effects of difficult labour. Prof. Couvelaire calculates that nearly half the deaths of infants during pregnancy are due to syphilis (41 per cent. of unmistakable syphilis, 17 per cent. of suspected syphilis), and one-sixth are due to other pathological conditions. He publishes some interesting graphs showing the influence of modern specific treatment on syphilis complicated by pregnancy. At the Baudelocque Hospital the death-rate among syphilitics during the first year of life was 62 per cent. when the mother and infant were not treated, it was 26 per cent. when the mother, but not the infant, was treated, and it was only 5 per cent. when both mother and infant were given specific treatment. The pre-natal mortality from syphilis during the last three months of pregnancy also varied greatly, according as the mother was or was not treated. In the first case it was only 30 per cent., whereas it was 70 per cent. when the syphilis, contracted during pregnancy, was not treated. When the syphilis of the mother was of old standing the infant mortality during the last three months of pregnancy was only 8 per cent. when the mothers were given specific treatment, whereas it was 20 per cent. when the mothers were not treated.[1]

---

[1] The World's Health, March, 1925.

Early in 1919 Prof. Couvelaire and Dr. M. Pinard opened a dispensary for the diagnosis and treatment of congenital diseases attached to the Baudelocque Hospital, and there are now 28 such dispensaries under the supervision of specialists in obstetrics and syphilis and subsidised by the Ministry of Health. Attached to the Baudelocque Hospital there is also a small maternity home reserved for mothers suffering from tuberculosis and connected with the system of isolating new-born infants from their parents, associated with the names of Grancher and Leon Bernard. Though much has been done in France for infants both before and after birth, Prof. Couvelaire insists that there is still plenty of room for improvement, and he would like to make the early notification of pregnancy compulsory so that timely measures could be taken to prevent disasters which cannot be averted when a medical examination is not made before birth. The examinations he would like to see introduced include, among others, an early obstetrical examination, tests of the urine for albumin and the blood for a Wassermann reaction, radiography, and measuring the blood pressure. He is surely not exorbitant in his demand that "future mothers should have, at least, the same care as that given by breeders to domestic animals."

A Legal Aspect of Gland Grafting for Cretinism.

Dr. Le Fort, who distinguished himself during the war by the skill with which he abstracted bullets and pieces of shell from the neck, has recently got into difficulties with the law on account of a thyroid grafting operation. The donor of the gland was a guillotined criminal, and the recipient was a child suffering from myxœdema and cretinism. Complete success has apparently attended Dr. Le Fort's efforts. The child, a girl 2½ years old, was emotionally inert at the time of the operation, and the first sign of success was observed when she burst out crying, for the first time in her life, on being deprived of a doll which had been given her a few days earlier. She can now laugh and cry. Dr. Le Fort is satisfied with his operation from the strictly scientific and humanitarian points of view. But, unfortunately for Dr. Le Fort, there are other factors in the world besides science and the relief of suffering. There is, for example, the law. And it appears that the authorities are perplexed as to what action to take. They ask: Had Dr. Le Fort the right to purloin any of the appurtenances of the criminal without having first obtained his permission? It might be argued that the criminal had no rights in this matter; that the State having possessed itself so completely of him as to decapitate him, it is rather with the State than with the criminal that Dr. Le Fort has fallen foul. The matter is of some practical importance, as gland grafting seems still to be in the fashion at the present time.

Oculists versus Opticians.

An interesting action between the Paris Medical Society and the Society of Opticians has just been decided before the Ninth Court of Paris. An optician had carried out an ophthalmoscopic examination in order to determine what glasses a person, who had gone to him for advice, should wear. The oculists argued through their society that, by using such a method, the optician had been guilty of the illegal practice of medicine. The Court finally accepted this view, giving judgment against the optician. The case is of interest for this, among other reasons, that it shows how with us, as with you in England, oculists and opticians do not always see eye to eye.

ROYAL MEDICAL BENEVOLENT FUND BALL.—The Kensington division of the British Medical Association is promoting a ball, the profits on which will be given to the Royal Medical Benevolent Fund and its Guild. Under the patronage of H.R.H. Princess Louise, Duchess of Argyll, the ball will take place on Thursday, May 7th, from 9 P.M. to 2 A.M., at the Kensington Town Hall, and tickets, at 1 guinea each or six for 5 guineas, can be obtained from the honorary secretary, Dr. Howard Stratford, 20, Upper Phillimore-place, Kensington, W. 8.

BUCHAREST.

(FROM OUR OWN CORRESPONDENT.)

Deaths Ascribed to Neosalvarsan.

SEVERAL deaths have occurred lately in Roumania following the administration of neosalvarsan. The first case occurred in Targoviste, where a military officer died 36 hours after the intravenous injection of 0·60 g. of neosalvarsan. His death started a great press agitation, in which the neosalvarsan preparation was indicted as the cause of the fatal issue, and certain newspapers even went so far as to say that the Germans were selling poisonous preparations to Roumania in order to devastate the Roumanians. The *Lupta*, a daily paper of good repute, writes as follows: "It is impossible to inundate the whole world with such preparations without the knowledge of the German factory, because several such cases occurred also in France. It is possible, therefore, that we have to deal with a terrible revenge against the Allies, or an unheard-of crime committed by carelessness." Other journals, more moderate, demanded thorough investigation. Thereupon the head of the sanitary department of the Ministry of War travelled to Targoviste. The analytical examination of the organs of the deceased revealed that death was due to the erroneous combination of the preparation. In the two fatal cases which occurred in Bucharest shortly after the above case, post-mortem examinations revealed that the fatal issue was attributable to a faulty preparation of the drug. The Minister of Public Heath has ordered that specimens shall be taken from all the wholesale drug-stores of the land and that these be analysed in the State chemical laboratory. The matter was also brought up in the Senate, where M. Saveanu, Minister of Public Health, replied that everything would be done in order to find out how the harmful preparations got into the country, and that any guilty parties would be adequately punished. On the same occasion the Minister said that a new law would be formulated regulating the admission of foreign preparations into Roumania, and those not on the list of permissible preparations would be confiscated in the Custom houses. The medical papers of Roumania are unanimous in saying that the preparations which have caused the deaths in question must have been smuggled preparations, which are cheap imitations of the original neosalvarsan, and are manufactured wholesale, but not in Germany.

A Strange Method of Controlling Doctors' Incomes.

The financial director of the tax office in a city in the Banat (a province in Roumania) has invented a novel method of controlling the income of physicians, from the point of view of taxation. He has sent a circular to all pharmacists in his district, ordering them to keep special ledgers for noting the prescriptions written by medical men and to submit the list at the end of every quarter to the tax office for inspection. The medical and pharmaceutical press is very much embarrassed by this proposal, which looks likely to injure friendly relations between physicians and pharmacists. They say that the system is valueless as an index of the physician's income, because if, for instance, Dr. X. writes 500 prescriptions in a year, the ledger will display more than 2000 prescriptions under his name, since the patients, as a rule, repeat one prescription four or five times. On the other hand, a surgeon may earn five times as much as a physician, although he does not write the fifth part of the prescriptions a physician does. Such a system would surely only tempt doctors to avoid writing prescriptions, even in cases where domestic medicines were out of place.

Roumanian Insulin.

Dr. Nitescu, professor of physiology at the University of Cluj, has invented a method whereby he is able to produce a very pure quality of insulin. The preparation, he claims, exceeds all other European insulins in efficacy and is equal to the Toronto insulin. The preparation has been given a trial in the clinics of the Cluj, Bucharest, and Jassy Universities. The results obtained were equal to those obtained with foreign-made insulins. Prof. Nitescu, however, has refused all commercial offers made by foreign concerns, as he wants to control the manufacture of his insulin himself.

The Success of the Abortive Treatment of Gonorrhœa.

Dr. Marinescu, lecturer at the University of Bucharest, writes in the *Romania Medicala* that the successful result of abortive treatment of an incipient gonorrhœa depends upon nine conditions: (1) Treatment to follow coitus within 36 hours. (2) Normal incubation. With excessive virulence the incubation is shorter. (3) The urethral orifice not be red, nor swollen, these symptoms being the signs of great virulence. (4) No thick filaments in the urine, thin threads only are permissible. (5) The urine not turbid. (6) The microscopical examination must reveal the presence of extra-cellular gonococci only. (7) The patient must not have treated himself previously, because bad treatment endangers the success of the abortive treatment. (8) Abortive treatment must always be made by the doctor himself and never by the patient. (9) The treatment must be continued for 10 to 12 days. According to Dr. Marinescu, two therapeutic methods deserve our attention: the urethro-vesical irrigations and the urethral irrigations, or both combined. He advocates 10 per cent. argyrol solution. The first lavage serves to wash out the urethra and it has to be let out immediately, the second injection only is retained for 4 to 6 minutes. This has to be repeated 3 or 4 times a day. If the urethra becomes tender during the course of treatment, and the first part of the urine contains purulent filaments, the irrigations have to be applied less frequently. The treatment has to be continued for at least 10 to 12 days, even if the secretion becomes gonococcus-free earlier. The success of the treatment can be promoted by the administration of internal urinary antiseptics and vaccines.

Conference for Defeating Malaria.

The Supreme Sanitary Commission held a conference in the last week of March in Bucharest to discuss the best methods of successfully exterminating malaria from Roumania. Most of the clinicians of the Roumanian universities were present, and also very many rural doctors. The conference resolved, upon the proposal of Prof. Cantacuzino and Prof. Mezinicescu, to hold a course in the laboratory of Prof. Cantacuzino in Jassy, for the teaching of modern methods of fighting malaria. The courses will be attended by all laboratory doctors of Roumania in successive groups. One course lasts four weeks, and will be free of expense for those taking part. After the termination of the course the campaign against malaria will be commenced in all swampy parts of the country and especially in the swampy district of the Dobrudja.

DONATIONS AND BEQUESTS.—The late Mrs. Sarah Anne Morgan, of Blaenavon, Mon., left £1050 to the Cardiff Royal Infirmary and £100 to Dr. Barnardo's Homes.—Mr. Samuel Wild, cotton spinner, of Oldham, bequeathed 2000 guineas to the Oldham Infirmary for the endowment of two beds in memory of his wife and his sister Mary, 250 guineas to St. Dunstan's Hostel for the Blind, and 115 guineas to Henshaw's Asylum for the Blind.—Mrs. Alice Margaret Bowerman, of Bath, left £300 to Epsom College Benevolent Association, and £200 each to the Mineral Water Hospital, Bath, and the Combe Down Convalescent Home.—Mrs. Ann Zilah Newton, of Derby, who left £5970, subject to certain life interests, bequeathed her estate to the Derbyshire Royal Infirmary.

"Audi alteram partem."

HOW TO BLOW THE NOSE.

To the Editor of THE LANCET.

SIR,—With reference to a recent contribution on this subject, if this were properly understood and properly taught, I am certain that the health of innumerable poor catarrhal children who crowd our clinics would be immensely improved, and the number of ear cases greatly reduced. In a leading article in your issue of Feb. 14th you give a timely reminder of the hygiene of the nose, and you give careful instructions in, what you consider to be, the proper method of blowing the nose. Although you are in agreement with most text-books, nevertheless, in my opinion, it is not the proper method nor the safest method. Very many of the catarrhal cases have a one-sided block, of greater or less degree, due to septal deviation, polypi, hypertrophied turbinals, &c. So that your instructions "to close one nostril with a finger and blow steadily and strongly down the other and repeat the process through the other nostril" would result in the patient, during one of the efforts, blowing steadily and strongly against an almost completely blocked nose, a danger which you rightly say must be avoided. For many years I have urged that there is but one safe and efficient way of blowing the nose, and it is as follows. Take an inspiration through the mouth, close both lips, and blow down both nostrils. Repeat until the nose is clear. This should be the method after all douching. When a handkerchief is used it should be held loosely round the nose—no pinching of the nose. With these precautions there need be no anxiety about middle-ear infection per Eustachian tube.

I am, Sir, yours faithfully,

A. D. SHARP.

Leeds, April 11th, 1925.

CHOLECYSTECTOMY

AVOIDANCE OF INJURY TO THE COMMON DUCT.

To the Editor of THE LANCET.

SIR,—Recent correspondence anent intubation of the common bile-duct for stricture caused by maladroit operations in cholecystectomy, prompts me to crave for space again[1] to call attention to the most effective method for removal of a gall-bag—which eliminates all reasonable possibility of undue encroachment on the common duct.

1. The affected vesicle is seized by two strong pressure forceps by which it is drawn downwards and forwards by "opposite" assistants.

2. The peritoneal reflection at the junction of the liver and gall-bag is then lightly divided with a scalpel sufficient to admit the application of a roll of dry gauze which, within a few seconds, by rotatory action, freely separates the viscus from the fossa fellea down below the level of the orifice (gall-bladder) of the cystic duct.

3. A small sterilised tray is then placed beneath the protruding gall-bag, which is at once divided by the scalpel, between the forceps previously attached, and its contents evacuated.

4. A few more pressure forceps are then applied in order securely to grip the edges of the wound. These forceps, with the tip of the left index finger fixed in the orifice of the cystic duct, are grasped in the palm of the left hand, while with the right fingers a thorough examination of the cystic, common, and hepatic ducts is executed.

5. If a calculus is found in the cystic duct it is usually kneaded between the right fingers into the gall-bag, if found in the common duct the operator walks round[2] to the left side of the patient—and the assistant

---

[1] THE LANCET, Sept. 20th, 1913.

[2] The Annals of Surgery, August, 1922.

with whom he has changed places seizes the forceps on the gall-bag making due traction on the same—while the operator inserts his left index finger supine into the foramen of Winslow, by which he advances and fixes the common duct so as to admit of safe incision. This effected, the calculus is turned out. A further thorough examination of the common and hepatic ducts is now made between the left index finger posteriorly and the left thumb anteriorly, and if any more gall-stones are found they are coaxed between these fingers to the exit previously made in the common duct. This wound is not sutured—it invariably closes per se within 20 days.

6. Cholecystectomy. The operator standing on the right side of the patient—with the tip of the left index finger just fixed in the opening of the cystic duct, and with the forceps grasping the gall-bladder in the palm of the left hand—makes gentle downward and forward traction so as to admit of the assistant placing a stout ligature around the cystic duct, just proximal to the bulge made from within by the operator's left index tip. The gall-bag is then clipped away with scissors—and as this is being executed a new forceps is applied to the edges of the stump so as to be able subsequently to ligate any bleeding point. A large wisp of silkworm gut is introduced into the depth and the rest of the external wound closed by interrupted double silkworm-gut sutures.

I do not know of any more safe or rapid procedure in abdominal surgery.

I am, Sir, yours faithfully,
Buenos Aires, Feb. 1st, 1925. JOHN O'CONOR.

THE DISCOVERY OF THE "BACTERIOPHAGE."

To the Editor of THE LANCET.

SIR,—In "Martin Arrowsmith," reviewed on March 14th, the author gives the credit for the discovery of the phenomenon of bacterial lysis caused by a contagious filter-passing material to Dr. d'Herelle of the Pasteur Institute. You may remember, however, that in my paper on the Ultra-microscopic Viruses, which was published in THE LANCET of Dec. 4th, 1915, I described the fundamental characters of this lysin—or virus—associated with different bacteria. I showed that it was present in the intestinal tract of man and dogs, and in most specimens of glycerinated calf vaccinia lymph. I pointed out that it passed the finest porcelain filters, that it infected bacteria, and that it could be transmitted from culture to culture indefinitely, besides describing many other characters. I also discussed the nature of the substance, and considered the possibility of its being an ultra-microscopic virus, and of there being different varieties according to the species of bacteria infected. I suggested, moreover, that it would probably be found associated with the dysentery bacilli. At the time of the publication of the paper I was asked to undertake duties in the army in Salonika, and I had no opportunity to work out any additional details connected with the phenomenon, although when in Salonika the whole subject was discussed with the Canadian, French, and British medical officers there. The first work of d'Herelle on the "lysin," named by him the "bacteriophage," associated with the dysentery bacilli was not published until nearly two years after the appearance of my paper.

I am, Sir, yours faithfully,
F. W. TWORT.

The Brown Institution (University of London),
149, Wandsworth-road, London, S.W.,
April 14th, 1925.

⁂ We have referred to the matter in our columns as the Twort-d'Herelle phenomenon on more than one occasion.—ED. L.

HOSPITAL SATURDAY FUNDS.—The Metropolitan Hospital Saturday Fund last year raised a total of £107,342, an increase upon 1923 of £6577. The number of hospitals and other institutions benefited was 230. Birmingham Hospital Saturday Fund collected £57,760, an improvement of £4386. The committee announce that the abolition of the ticket system is being "seriously considered."

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, April 21st.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.
Annual General Meeting:
Election of Officers and Council for 1925–26.

GENERAL MEETING OF FELLOWS: at 5.30 P.M.
Ballot for election to the Fellowship.

Thursday, April 23rd.

EPIDEMIOLOGY AND STATE MEDICINE: at 5.30 P.M.
Paper:
Dr. Monckton Copeman: Immunisation against Scarlet Fever.

UROLOGY: at 8.30 P.M.
Discussion:
Bacterial Infections of the Urinary Tract.
Openers:
Prof. Leonard S. Dudgeon (Pathological), Dr. E. Lepper (Experimental), Sir John Thomson-Walker (Diagnosis and Treatment).

Friday, April 24th.

STUDY OF DISEASE IN CHILDREN: at 8.30 P.M.
Discussion:
Is the Modification of Cow's Milk Necessary in Infant Feeding?
Openers:
Dr. Leonard Findlay, Dr. Eric Pritchard, Dr. Hugh Thursfield, and Dr. R. C. Jewesbury.

ROYAL INSTITUTION, 21, Albemarle-street, W.
TUESDAY, April 21st.—5.15 P.M., Prof. J. Barcroft: Effects of Climate on the Circulation. (I.)

MEDICO-LEGAL SOCIETY (President: The Rt. Hon. Lord Justice Atkin), 11, Chandos-street, Cavendish-square, W.
TUESDAY, April 21st.—8.30 P.M., A paper will be read by the Rt. Hon. Lord Riddell on the Legal Responsibility of the Surgeon. To be followed by a discussion. Members may introduce guests on production of a Member's private card.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos-street, Cavendish-square, W.
FRIDAY, April 24th.—8.30 P.M., Papers will be read by Dr. H. H. Dale and Mr. David Lees on the Toxic Effects of Arseno-Benzol Treatment and Their Prevention. A Discussion will follow.

BRITISH PSYCHOLOGICAL SOCIETY (Medical Section) (at the House of the Medical Society of London, 11, Chandos-street, W.).
WEDNESDAY, April 22nd.—8.30 P.M., Dr. A. Wohlegemuth: The "Synthesis" of an Anxiety-Neurosis.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.
MONDAY, April 20th.—11 A.M., Surgical Registrar: Surgical Wards. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Dr. Scott Pinchin: Medical Out-patients.
TUESDAY.—11 A.M., Mr. Endean: Venereal Diseases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.
WEDNESDAY.—11 A.M., Medical Registrar: Medical Wards. 2 P.M., Dr. Burnford: Medical Wards. 2 P.M., Dr. Owen: Medical Out-patients.
THURSDAY.—11 A.M., Sir Henry Simson: Gynæcological Wards. 2 P.M., Mr. MacDonald: Genito-Urinary Dept. 2 P.M., Mr. Simmonds: Surgical Out-patients.
FRIDAY.—11 A.M., Dr. McDougal: Electrical Dept. 12 noon, Surgical Registrar: Surgical Pathology. 2 P.M., Mr. Sinclair: Surgical Out-patients.
SATURDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 10 A.M., Mr. Banks-Davis: Operations on Nose, Throat, and Ear.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.
FRIDAY, April 24th.—4 P.M., Dr. Andrew Wylie: Dysphagia.

MANCHESTER BABIES' HOSPITAL POST-GRADUATE LECTURES.
FRIDAY, April 17th.—8 P.M., Dr. Leonard Parsons: The Rôle of Fats in the Production and Treatment of Infantile Atrophy.

MANCHESTER ROYAL INFIRMARY.
TUESDAY, April 21st.—4.15 P.M., Dr. F. E. Tylecote: Hilum Tuberculosis.
FRIDAY.—4.15 P.M., Demonstration of Cases. Medical: Dr. F. Craven Moore. Surgical: Mr. J. Morley.

Parliamentary Intelligence.

HOUSE OF COMMONS.

Easter Recess.

Parliament adjourned on Thursday, April 9th, for the Easter Recess. It will reassemble on Tuesday, April 28th.

Monday, April 6th.

International Arsenic Imports.

Captain **Moreing** asked the President of the Board of Trade what quantities of arsenic were imported into the United Kingdom from countries other than Japan during December, 1924, and January and February, 1925, respectively, giving the countries of origin.—Mr. A. M. **Samuel** (Parliamentary Secretary to the Overseas Trade Department) replied: The following statement shows the quantities of arsenic and arsenic compounds imported into Great Britain and Northern Ireland and registered as consigned from the countries named during the months specified. The actual countries of origin as distinguished from countries from whence goods are consigned are not recorded in the trade returns of the United Kingdom.

Articles and countries whence consigned.	December, 1924.	January, 1925.	February, 1925.
Arsenic (Metal).	lb.	lb.	lb.
Germany	—	—	3360
Arsenic, White.	Tons.	Tons.	Tons.

France	31	—	—
Mexico	—	—	5

Scottish Vital Statistics.

The House went into Committee of Supply on a Vote of £1,976,885 for the salaries and expenses of the Scottish Board of Health.

Captain **Elliot** (Parliamentary Under Secretary for Health, Scotland) said that the public health record last year was unsatisfactory. The vital statistics moved adversely. The death-rate, which was 12·9 per 1000 in 1923, moved up to 14·4 per 1000 for 1924. The infantile mortality, which was 79 in 1923, moved up to 98 and the sickness statistics also moved in an adverse direction, the insurance returns showing a rise of from 15 to 20 per cent. all over. The tuberculosis death-rate, however, was as favourable, or slightly more favourable, than those of the previous year. He had investigated the returns as far as he could and it seemed that in Scotland, at any rate, they had moved adversely owing to an epidemic of influenza in the early part of the year. But the position was not so bad as it appeared from the figures he had just quoted. The infantile mortality increase seemed to have been due largely to epidemics of various kinds, and the death-rate, which was 132 in the first quarter of the year under review, was 109 in the current quarter of this year. That at any rate was an encouraging figure.

He did not think that they would have the healthiest year on record, but he hoped that the figures would not be so severe as they were in the previous year. The adult sickness was from 15 to 20 per cent. up. That held good in England as well as in Scotland. The vital statistics moved in the wrong direction, also in France and in Denmark, so that, oddly enough, a wave of ill-health had passed over Western Europe. The returns moved seriously against them in Scotland, something like 1·5; to a lesser extent in England, something like 0·6; to a slightly lesser extent in France, about 0·3; and in Denmark something like 0·1. Some people said that the cause of this simultaneous movement of the vital statistics in the wrong direction all over Western Europe was the sunless summer. He did not know. Certainly the expense of drugs went up tremendously in Scotland—to over 25 per cent.; it went up to £40,000 above the average requirements of the preceding four years, and what that was due to he did not know. The Board were making a grant in respect of measles, an increased grant for pneumonia and bronchitis, and investigations were being made into the cause of infective jaundice, which caused considerable anxiety among the mining population in the East of Scotland. The organism of infective jaundice had been discovered, and the circulars sent out calling attention to it had resulted in the diagnosis as due to this infective jaundice of several conditions which were previously put down to some state of ill-health following influenza. Oddly enough, the same thing appeared in dogs, where the jaundice following an infection by this organism was apparently paralleled by a similar infection which had previously been put down to a post-distemper infection. Apparently it was a disease of rats, to which dogs were also subject, as well as human beings, and it was not merely an industrial disease, but one of which there were a certain number of cases among the rank and file of the population. They had made it notifiable in Scotland.

The difficulty in discussing Scottish vital statistics was that they could not get the people fully to understand how enormously important they were to the life of the community. The declining population of France, for instance, was not due to the low birth-rate but to the high death-rate. The death-rate in France was 17·3, as against something in the nature of 12 for England and Wales. The real policy was determined by the medical officers of health and the other people who worked out the amount of the new population who were going to survive. If the French gave up making 75 mm. guns and took to buying drain-pipes from Paisley they would be a much more formidable nation than at present.

Dr. **Drummond Shiels** asked if the Scottish Board of Health had given any consideration to the introduction of the Spahlinger treatment for tuberculosis. With some other medical Members of the House he had seen a number of cases treated with the new serum and vaccine last week in London and he was very much impressed with them. He knew there were difficulties in the way at present, but he would ask Captain Elliot to encourage his department to coöperate with the Ministry of Health in endeavouring to get some method by which this treatment could be given to sufferers. He did not think they should wait until the treatment was finally and absolutely guaranteed. As regarded the forms of tuberculosis other than pulmonary, he asked Captain Elliot to encourage the treatment of heliotherapy. He thought that the light treatment of tuberculosis was going to be very important, especially in surgical tuberculosis, which included practically all other forms than those associated with the lungs. Light treatment was proving very effective in the City Hospital in Edinburgh. Lupus or tuberculosis of the skin was a very terrible form of disease which very often affected young women most frequently in the face, and if it was not checked it created tragedy which was much worse than death. The Board of Health would do a very useful work in encouraging local authorities to see that the light treatment of this terrible disease was encouraged.

Recently in Edinburgh 403 samples of milk were taken, and 33 of them, or 8·1 per cent., contained live tubercle bacilli; the figures in other towns were very similar. The tuberculosis officer for Edinburgh gave figures in 1922 showing that of all the gland cases 30 per cent. were due to bovine tubercle, 18 per cent. of all meningeal cases, 50 per cent. of all abdominal tuberculosis cases, 58 per cent. of cases of tuberculous bones and joints, and 50 per cent. of lupus cases were due to the bovine bacillus which was practically always transmitted through milk. He was glad that the Board had realised its importance, and he urged that they should bring in at the very earliest moment the Tuberculosis Order of 1914. He wished to ask if anything had been done to carry out the recommendations of the local authorities received in a deputation in 1923 with a view to giving those authorities more power to deal with venereal disease. In the year ending May, 1923, the total attendances at the clinics in Scotland were 289,945, involving 22,800 people. These did not, of course, cover all the cases.

The hon. Member also called attention to the cases of ophthalmia neonatorum. It was disappointing to find in the weekly health returns that these cases were frequently occurring. It was well known that they need not occur. The treatment for prevention was extremely simple, and in many cases on the birth of a child this prophylactic treatment was given in institutions and by private practitioners. A great proportion of the cases of blindness in this country was due to this disease and it was very desirable when it was entirely preventable that the Board should be a little more stringent, and see that it did not appear in the weekly health statistics. Between 30 and 40 per cent. of the cases of infantile mortality were due to premature birth and congenital debility. That was nearly always due to the condition of the mother. These causes were the most important of the causes of infantile mortality and the condition of the mother before the child was born was thus of fundamental importance. In many towns of Scotland child welfare centres and antenatal centres were not properly accommodated. He thought the Board should give a little more attention to this matter. They had refused to extend these centres in many cases. With regard to the nutrition of school-children in 1923, 16,200 children were officially certified as having a state of nutrition below the average, and 600 were certified as having very poor nutrition.

Captain Elliot, replying to the debate, said that the Board of Health had two officers investigating treatment by light at present. They would do their best to see that this most fascinating and stimulating subject was fully explored, and the full advantage taken of it for Scotland.

The debate was adjourned.

TUESDAY, APRIL 7TH.

Pay and Pensions of R.A.M.C. Officers.

Sir Philip Richardson asked the Secretary of State for War whether he was aware that, after allowing for income tax and the increased cost of living, the pay and pensions of medical officers, and particularly those in India, were smaller in purchasing power than in 1914; whether he was aware that this was the cause of the falling off in the number of entrants to the Royal Army Medical Corps; and whether he proposed to recommend adequate increases.—Sir L. Worthington-Evans replied: The falling off in the number of candidates for the Royal Army Medical Corps is due to several causes with which I could not deal within the limits of a Parliamentary answer. I hope that it will be possible to find a remedy without undue delay.

Chemical Warfare Experiments.

Mr. Ammon asked the Secretary of State for War if the 188 soldiers subjected to poison-gas experiments at the chemical warfare research department since 1918 included officers; and what were the number of officers and men, respectively, subjected to such experiments. — Sir L. Worthington-Evans replied: The answer to the first part of the question is in the negative. The total number of officers and men of the navy and army subjected to the tests during the period in question is: Officers, 317; other ranks, 207.

Medical Re-examination of Pensioners.

Mr. Hayes asked the Minister of Pensions whether, in those cases considered for final awards and not found suitable and who were given an award for one year until further instructions, it was intended that they should draw the present pension without re-boarding unless the pensioner submitted a claim for increase of pension on the ground of deterioration.—Lieut.-Colonel G. F. Stanley (Parliamentary Secretary to the Ministry of Pensions) replied: It is the policy of my right hon. friend, as it was also that of his predecessor, to reduce to a minimum the frequent medical re-examination of pensioners who have been on the pension list for four years or more, and the award referred to was designed to extend the period of review in cases where a final award could not be made. Cases will be liable to review with due regard to the nature of the disability and other factors, and while a substantial number of them will probably not be again examined by a medical board, except in the circumstances stated, others will, if it is thought advisable, be re-examined by a board at suitable intervals.

Milk for Mothers and Young Children.

Mr. W. C. Robinson asked the Minister of Health what local authorities were now providing milk for mothers and young children.—Sir Kingsley Wood replied: According to the information in my right hon. friend's department, this service is now provided by 426 local authorities in England and Wales.

Maternity and Child Welfare.

Colonel Day asked the Minister of Health if there were any boroughs or counties that had made no provision for maternity and child welfare; and, if so, would he give the names of the boroughs and counties, and say what action he proposed to take for their introduction.—Mr. N. Chamberlain replied: The answer to the first part of the question is that provision for maternity and child welfare may be made either by the county council or by the local sanitary authority, and such provision has been made for every sanitary district in England and Wales. The last part of the question, therefore, does not arise.

Morphine, Heroin, and Codeine Manufacture.

Colonel Day asked the Home Secretary how much opium was purchased by factories in Great Britain during the year 1924; how much morphine; how much heroin; how much codeine was manufactured by the manufacturers in Great Britain during 1924; and how much of each of these narcotics was sent abroad.—Sir W. Joynson-Hicks replied: The compilation of the statistics for 1924 is not yet completed and I am able at the present moment to give only the figures of manufacture asked for, which must be regarded as provisional. They are as follows: Morphine, 99,400 oz.; heroin, 16,700 oz.; and codeine, 153,300 oz.

WEDNESDAY, APRIL 8TH.

MENTAL DEFICIENCY (AMENDMENT) BILL.

The Mental Deficiency (Amendment) Bill was read a second time.

This measure, which has been introduced by Sir Leslie Scott, and is backed by Mr. Fisher, Sir Henry Slesser, Lieut.-Colonel Fremantle, and Mr. Herald Hurst, amends Section 7 of the Mental Deficiency Act, 1913, for the purpose of enabling a defective to be removed from an institution in order to be placed under guardianship. In the Memorandum attached to the Bill it is explained that some defectives after prolonged residence in institutions improve sufficiently to permit of their being sent out of the institution if some arrangements are available for providing care and supervision for them outside. The existing law does not allow of transfer from an institution to guardianship, but only from guardianship to an institution. If it is desired to transfer a case from an institution to guardianship it is at present necessary to discharge the patient and to take all the proceedings necessary to obtain a new order. These proceedings are cumbrous and expensive. Sir Leslie Scott's Bill provides that the same machinery which is available for transferring cases from guardianship to institutions shall be available for the reverse process.

Venereal Disease Grants.

Major-General Sir John Davidson asked the Minister of Health if an annual grant of money was made to the National Council for Combating Venereal Diseases; if so, what was the amount; whether any return was made to the Ministry showing in detail how it was expended; and if such return was available for public information.—Mr. N. Chamberlain replied: The reply to the first and third parts of the question is in the affirmative. As regards the second part, the amount of the grant varies from year to year and was £9183 for the last financial year. As regards the last part of the question, details of the expenditure of the grants are shown in the annual reports published by the National Council.

Pay of Women in Civil Service.

Mr. Trevelyan Thomson asked the Home Secretary how many women in his department were performing the same work as men and receiving equal pay; how many were performing the same work and not receiving equal pay; and what was the reason for the differentiation.—Sir William Joynson-Hicks replied: One medical inspector of factories receives the same rate of pay as the men performing the same duties. There are 39 other women employed by the Home Office in grades open to men and women whose remuneration follows the general principles already enunciated by the Financial Secretary to the Treasury. In the case of 14 women factory inspectors, the scale for women is identical with that for men so far as regards the lowest grade in the inspectorate.

THURSDAY, APRIL 9TH.

Charges Against Pensions Officials.

Sir Wilfred Sugden asked the Minister of Pensions whether he had inquired into the statement made on Feb. 17th in that House by the hon. and gallant Member for Salford West, to the effect that the assessors in the North-Western Region were required by the regional awards officer to reduce a certain number of pensions weekly; that if they affirmed or, in some cases, increased the assessment the regional awards officer sent for them and inquired why they had not produced the regular quota of reductions; and, if he had made such an inquiry, what was the result of his investigations.—Major G. C. Tryon replied: I have made careful inquiry into this allegation and am satisfied that there is no foundation whatever for it. The hon. and gallant Member for Salford (Mr. Hugh Morrison) has given me no assistance, but I have had full reports from the Regional Director, the Commissioner of Medical Services, the Regional Awarding Officer, and the Medical Assessors, all of whom deny the charge absolutely. I need scarcely add that any such practice would be entirely contrary to all instructions, and indeed impossible under the existing organisation of the Regional Office.

Pensioners and Treatment Allowances.

Colonel Day asked the Minister of Pensions whether, seeing that under the rules of the Ministry a man suffering from attributable disabilities which disabled him from work was not entitled to treatment allowance, unless the treatment prescribed by the Ministry was of such a character as actually to prevent him from obtaining work, and in view of the fact that a man certified by his panel doctor or by a hospital board to be incapable of work was thereby rendered incapable of obtaining work, and at the same time was receiving no treatment allowance, he would take steps to remove what appeared to be a great hardship to ex-Service men.—Major Tryon replied: I would remind the hon. and gallant Member that (as was stated in reply to a similar question on July 28th last) the conditions governing the grant of allowances under Article 6 of the Warrant are not identical with those which determine certification for the purpose of sickness benefit under the National Health Insurance Acts. Allowances under the Warrant are not, therefore, necessarily also payable in all cases, because sickness benefit is obtained. I am not, therefore, in a position to accept the hon. Member's suggestion.

The Development of Garden Cities.

Mr. **FENBY** asked the Minister of Health whether, in view of the ascertained facts that garden cities had now passed the experimental stage and was a profitable investment of public money, that they relieved congestion of population and traffic, took manufactures and workshops into the country, supplied houses for all classes, showed satisfactory health statistics, stimulated agriculture, horticulture, and market gardening and allotments, created new markets, and developed mentally and physically a vigorous and contented population, he would take steps to appoint garden city commissioners with powers to raise capital, acquire sites, issue loans, and in all possible ways facilitate the establishment of garden cities.—Sir H. **BARNSTON** (Comptroller of the Household) replied: My right hon. friend has every sympathy with the development of estates on garden city lines, and is watching with interest the progress which is being made; but in his opinion further experience is necessary before considering the establishment of special machinery such as the hon. Member suggests.

Salary of Pensions Department Medical Officers.

Colonel Sir **ARTHUR HOLBROOK** asked the Minister of Pensions whether the increase of salary of £50 per annum to be given to full-time medical officers of the Ministry whose services were being retained was in lieu of bonus or gratuity; and, if not so granted, would he explain why it was granted, seeing that the work had been and was steadily diminishing in comparison with that of the past five or six years.—Major **TRYON** replied: The increase in question is not of the nature either of a bonus or a gratuity, but is part of a general revision of the rates of remuneration of the administrative medical staff of the Ministry. In regard to the last part of the question, I would point out that while the work of the Ministry as a whole has diminished, the staff has also been reduced to a corresponding extent, and the work and responsibilities of individual officers remain as great as before.

Widows and Orphans in England and Wales.

Colonel **DAY** asked the Minister of Health the number of widows in England and Wales; and, if possible, the number of fatherless children and orphans under 14 years of age, respectively.—Mr. N. **CHAMBERLAIN** replied: For England and Wales the desired figures according to the 1921 Census were as follows:—

—	Widows.	Children under 14 years.		
		Father dead.	Mother dead.	Both parents dead.
England	1,528,093	613,531	208,581	43,548
Wales and Monmouth	93,665	41,224	20,615	3,297
Total	1,621,758	654,755	229,196	46,845

White Lead Poisoning.

On the motion for the adjournment of the House for the Easter Recess until April 28th,

Mr. **RHYS DAVIES** raised the question of the attitude of the Government to the International Labour Conventions. He said that the growth of the number of cases of lead poisoning was rather disturbing. In 1922 there were 246 cases and 26 deaths; in 1923, 327 cases and 25 deaths; and in 1924, 486 cases and 32 deaths. The Labour Party desired to see a Bill introduced entirely prohibiting the use of white lead in paint. He asked that the question of anthrax should not be dropped, and that steps should be taken to appoint Dominion delegates so that this subject might be raised on behalf of the Empire at Geneva.

Sir W. **JOYNSON-HICKS**, Home Secretary, said there were great difficulties in dealing with the question of white lead, as there were two schools of thought, one which desired to prohibit its use altogether, and the other which wanted to regulate it. He hoped to bring in a Bill, which was already in draft, directly after Easter, and that agreement would be reached among the users and the manufacturers of white lead so that he would be able to make regulations. These regulations would deal with the present methods of painting buildings and prohibit the use of white lead except in the form of paste and paint ready for use. They would also deal with the danger arising from the rubbing down or scraping of old paint, and prohibit altogether, or modify, the periods during which young persons might work with white lead. He would give the House this further undertaking that if experience of the working of the regulations proved that they did not carry out what was hoped, and did not enormously diminish the illness and deaths that arose from the use of white lead, he would come to the House and ask for further powers. As to the danger of anthrax arising from imported wool, the Government disinfecting station at Liverpool was doing good work in minimising the danger. The Government were anxious to have it established that all wool should be disinfected before it came to this country. But the Geneva Conference would not pass such a proposal, and it rejected by 50 votes to 41 a motion by Mr. Rhys Davies himself to have the question raised again by placing it on the agenda of this year's meeting. The Empire was not unanimous. The Government were willing to try to get the Empire to agree, but the hon. gentleman knew the difficulties.

Sir A. **STEEL-MAITLAND**, Minister of Labour, said that the reason why the Maternity Convention had not been ratified was that it was generally considered that the position of married women in this country under the National Health Insurance Acts was different from that provided in the Convention, and on the whole secured them as favourable conditions.

Medical News.

UNIVERSITY OF LONDON: SENATORIAL ELECTION.—The nominations for Representatives of Convocation on the Senate of the University have now gone in, and in the Faculty of Medicine Dr. Graham Little, the Member of Parliament for the University, is opposed by Mr. T. B. Layton, who stands with the support of the Twentieth Century Society of London Graduates. Dr. Graham Little being the President of the University of London Graduates Association, the election may be presumed to be a trial of strength between the two bodies, the main point at issue being the adoption or rejection of the Haldane Report.

Three lectures on Recent Advances in the Study of Living Cells will be given at King's College, Strand, London, W.C., by Prof. Robert Chambers, professor of microscopic anatomy in Cornell University, New York, on April 27th, 28th, and 29th, at 5.30 P.M. Admission to these lectures is free.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH.—At the recent dental examinations, just concluded, out of 26 candidates entered the following 13 passed the Final Professional Examination and were granted the diploma L.D.S. R.C.S. Edin.:—

David Lumsden, Thomas D. Gould, Douglas B. Cruickshank, Annie M. Stephen, Temple F. M. Gibson, John W. Swan, Peter Adair, Edward P. Tait, John Shearer, James McK. Proctor, Norman G. Imlach, John D. Cooper, and Robert J. Snodgrass.

The following candidates passed in the subjects of—

Pathology.—Esmee K. Wilson, Pieter F. Zuidmeer, and Walter E. Phillips.

Medicine and Surgery.—Esmee K. Wilson, Guthrie Russell, and Mela R. Soni.

Dental Subjects.—John Baker.

UNIVERSITY OF ABERDEEN.—At the graduation ceremony held recently, degrees in medicine were conferred on the following successful candidates:—

DOCTOR OF MEDICINE.

Martin M. Cruickshank (in absentia) (awarded honours for thesis), Richard R. Trail (awarded commendation for thesis), John MacLennan (old regulations), and Alexande Mitchell.

BACHELOR OF MEDICINE AND BACHELOR OF SURGERY.

With Second-class Honours.—*Charles S. D. Don, *William A. Mair, *James A. R. Paterson, and Donald S. Stewart.

Ordinary Degree.—*Philip Bayer, Henry C. Bonney, William Booth, Leon Chanock, *Alexander Cruickshank, Ronald A. Cumming, John M. Davidson, Gilbert M. Davis, Charles A. Dean, Jessie R. G. Dingwall, Albert T. Duncan, George N. Duthie, Margaret M. Gair, Alexander Galloway, James A. Gordon, John D. Gordon, Thomas R. Gordon, Janet Johnston, William Kelly, David B. Laing, John MacArthur, *Patrick D. A. MacDonald, Kenneth C. MacKenzie, Donald N. MacKinnon, Frank S. McLean, Anne G. I. MacLennan, George W. Mearns, Lewis Morgan, James A. Mulligan, Norman M. Munro, Oswald G. Prosser, William J. Raitt, William P. E. Richards, James Robertson, *Maurice C. G. Robertson, Albert A. Simpson, *John T. Sorley, William R. Soutter, Barbara W. Spark, John I. Taylor, Hector M. Walker, James D. Walker, *Richard W. H. Welsh, Adam D. F. White, Alexander H. Wilson, Charlotte M. Wilson, and Douglas E. Wilson.

* Completed Final Medical Professional Examination with distinction.

DIPLOMA IN PUBLIC HEALTH.

Agnes M. E. Benzie, John C. Kerrin, Christina R. Laing, John C. Milne, Lily M. Watt, and Mabel Wilson.

HUNTERIAN SOCIETY.—The annual general meeting of this society has unavoidably been postponed, and will now take place on May 11th, at Simpson's Restaurant, Cheapside, London.

THE Royal Academy of Sciences of Copenhagen has nominated Prof. E. H. Starling, Foulerton Research Professor of the Royal Society, a foreign member of the Physiology Class.

ROYAL INSTITUTION.—A general meeting of the members of the Royal Institution was held on April 6th when the special thanks of the members were returned to Sir Humphry Davy Rolleston for a gift of a large number of letters from Sir Humphry Davy.

FREEMASONS HOSPITAL AND NURSING HOME.—The following have been appointed as members of the honorary consulting staff: Dr. Newton Pitt, Sir James Purves-Stewart, Mr. A. Baldwin, Mr. Ernest Clarke, Sir James Dundas-Grant, Mr. T. H. Openshaw, Sir D'Arcy Power, and Mr. Percy Sargent. Sir D'Arcy Power has been appointed chairman of the Medical Advisory Committee of the Institution.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At the monthly meeting of the Faculty, held on April 6th, Drs. James P. Brown, Arthur C. L. La Frenais, and Thomas M. Newton were admitted, after examination, as Fellows of the Faculty.—At the same meeting the Faculty elected Dr. James A. Adams as their representative on the General Medical Council for the period of five years.

UNIVERSITY OF BIRMINGHAM.—A three months' course of post-graduate demonstrations will be given at the General Hospital, Birmingham, on Tuesdays, and at the Queen's Hospital, Birmingham, on Fridays, from 3.30 to 5 P.M., commencing on April 21st. The course will include demonstrations on medical and surgical cases, skin diseases, ophthalmic cases, children's diseases, urinary diseases, insulin treatment, &c. Further information may be obtained from the Clerk to Clinical Board, University, Edmund-street, Birmingham.

TAVISTOCK CLINIC.—A course of ten lectures on the Treatment of Functional Nerve Disease will be given at the Tavistock Clinic for Functional Nerve Cases by Dr. H. Crichton-Miller, Dr. S. Roodhouse Gloyne, and Dr. J. R. Rees, on Tuesdays, at 5.30 P.M., beginning May 5th. A syllabus of the lectures and further details may be obtained from the hon. lecture secretary at the clinic, 51, Tavistock-square, London, W.C. 1.

BRITISH EMPIRE CANCER CAMPAIGN.—The following grants have been made: £2500 to the Cancer Research Department of the Cancer Hospital (Free); £3000 for cancer research purposes to the Middlesex Hospital; £400 to St. Mark's Hospital, City-road, for further cancer investigations; £500 to Dr. Thomas Lumsden, of the Lister Institute, for original cancer research; £300 to Dr. Malcolm Donaldson to facilitate research into certain forms of inoperable cancer; £1695 to St. Bartholomew's Hospital for the formation and maintenance of a special radiology research department into cancer; and £1400 (additional) to the Middlesex Hospital for similar purposes, subject to the confirmation of the Radiology Committee of the Medical Research Council. These sums are additional to grants in furtherance of cancer research of £6480 made during the current financial year and are exclusive of the sum of £5000 for radium for the use of various institutions and organisations.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.—A meeting was held at the Miller General Hospital, Greenwich, on April 3rd, with Dr. H. S. Knight, the President, in the chair, when an address and demonstration on Anæsthetics for Operations in the Region of the Mouth and Nose was delivered by Mr. E. Stanley Rowbotham, of the Sidcup War Hospital. The speaker described the method by which two catheters were used for intubation of the larynx, one for insufflation into the trachea, and the other, the larger, for expiration. The catheters were tied together and passed as far as the bifurcation of the trachea. A free airway and absence of septic lung trouble resulted. The supply of the air current might be provided by a cylinder of compressed gas, an electric motor, or bellows. The anæsthetic vapour required to be warmed as it passed direct to the lungs. An anæsthetic was first given in the ordinary way, then the direct laryngoscope was used and the tubes were passed. For the nasal passage an adrenalin spray was used. Double intubation was necessary for mouth and tongue operations. Chloroform had to be used in diathermy operations in order to avoid the risk of an explosion. The lecturer then demonstrated the mechanism of the different pieces of apparatus.

MEDICAL HYDROLOGY.—Under the auspices of the Committee for the Study of Medical Hydrology in England, a course of lectures and demonstrations will be held in the Senate room of the University of London, from April 27th to 30th. Lectures will be given by Dr. J. C. Thresh on Types of Water, Mr. Dewey on Hydro-geology, Prof. J. Barcroft on the Capillary Circulation of the Skin, Dr. Fortescue Fox on Heat in the Treatment of Disease, Dr. J. B. Burt on Disorders of Digestion, Dr. V. M. Coates on Arthritis, and Dr. Rupert Collins on Neurasthenia, followed by a visit to Buxton. Those proposing to be present at the lectures or at Buxton are asked to notify the hon. secretary, Hydrology Committee, University of London, South Kensington, S.W. 7.

THE LATE DR. C. W. HAYWARD.—Charles Williams Hayward, M.D. Edin., D.P.H. Camb., died on April 3rd, at Meigle, Perthshire, aged 60. He was born at Vernon House, Mount Vernon-road, Liverpool, and was the son of the late Dr. John W. Hayward, of Liverpool. He joined his father in practice there soon after qualifying M.B., C.M. at the University of Edinburgh in 1886. He studied at the University of Edinburgh and Vienna, and became M.R.C.S. and L.R.C.P. London in 1888. In 1889, at the University of Edinburgh, his thesis for M.D. was considered worthy of commendation. A man of singularly varied acquirements and great versatility, he was physician, musician, playwright, politician, and a barrister-at-law of Gray's Inn. He was called to the Bar in 1898, but did not practise. His father was an ardent Liberal and Dr. Hayward carried on the political traditions in support of that party in Liverpool. In 1914 he was selected by the Liberals to stand for the Eddisbury Division, but was not elected to Parliament. He was an enthusiastic supporter of the National Insurance Act. Besides some contributions to medical literature, he was the author of two plays dealing with Rome of the classical era, and collaborated in writing a musical comedy. He was an honorary physician of the Liverpool Hahnemann Hospital. His remains were cremated at Glasgow on April 7th.

THE LATE DR. J. DULBERG.—Joseph Dulberg, M.D. Würzburg, who was born in Roumania 63 years ago, was a well-known figure in Manchester medical circles, more especially amongst the Jewish community, where his activities were manifold. Two years ago his health broke down and he retired to Southport, where he died on April 8th in his sixty-fourth year. He left Roumania when a young man, went to Berlin, where he studied law, graduating as Doctor of Law in 1882. He then went to Manchester, where his father had established himself in business, and studied medicine at Owens College. He completed his medical studies at Würzburg, where he graduated M.D. in 1891, and having obtained the L.S.A. in 1892 began practice in Manchester. Dr. Dulberg was one of the founders of the Jewish Hospital in Manchester, of which he was an honorary physician. He acquired an intimate knowledge of hospital work when a resident assistant physician at the Julius-Spital in Würzburg. Dr. Dulberg was a prolific writer on medical subjects. In 1905 he translated Senator and Kaminer's book in two large volumes on "Health and Disease in Relation to Marriage and the Married State," besides writing on "Personal and Family History in Relation to Life Insurance," "Continental Spas," and "Sterile Marriages." In 1915 he volunteered for military service and was in charge of the Seaforth Military Hospital, and afterwards of the Neurasthenic Hospital at Brinnington, near Stockport, and was prominent in the territorial movement promoted by Israel Zangwill. He took a keen interest in psycho-therapeutics. He was a J.P. of the city of Manchester and a magistrate for over 16 years.

Appointments.

DONALD, H. G., M.B., Ch.B. Aberd., has been appointed Medical Officer of Health, Auckland Rural District Council.

FRASER, J., M.D., Ch.M., F.R.C.S. Edin., Professor of Clinical Surgery in the University of Edinburgh.

PARROTT, A. H., M.D.S. Birm., L.D.S. R.C.S. Eng., Lecturer in Dental Materia Medica and Therapeutics at the University of Birmingham.

SMITH, H. G., M.D. Lond., D.P.H., Medical Officer of Health, School Medical Officer, and Police Surgeon, Lincoln.

TAYLOR, A. L., M.B., Ch.B., F.R.C.P. Edin., Senior Assistant Medical Officer at the County Mental Hospital, Burntwood, Lichfield.

Royal Alexandra Infirmary, Paisley: CALDWELL, J., M.B., Ch.B. Glasg., Resident House Physician; POLLOCK, A. M., M.B., Ch.B. Glasg., GILLIES, D. R., M.B., Ch.B. St. And., Resident House Surgeons.

Vacancies.

For further information refer to the advertisement columns.

Barnet, Wellhouse Hospital.—Res. M.O. £350.
Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.
Brighton, Sussex Throat and Ear Hospital.—Hon. Clin. Asst.
Bury Infirmary.—Hon. Ophth. S.
Cairo School of Medicine.—Asst. Prof. of Chemistry. L.E.720.
Canterbury, Kent and Canterbury Hospital.—Third Res. M.O. £125.
City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—H.P. at rate of £100.
Colchester, Essex County Hospital.—Asst. H.S. and Reg. £150.
Dartford, Kent, City of London Mental Hospital.—Med. Supt. £1250.
Eastcote, Middlesex, St. Vincent's Orthopædic Hospital.—Res. M.O. at rate of £150.
East London Hospital for Children and Dispensary for Women, Shadwell, E.—Res. M.O. £200. Also H.P. at rate of £125. Also Morning Cas. O. at rate of £120.
Evelina Hospital for Children, Southwark, S.E.—H.S. at rate of £120.
Holland County Council, Lincolnshire.—Asst. County M.O. £600.
Leeds Public Dispensary.—Jun. Res. M.O. £150.
London Lock Hospital, 91, Dean-street, W.—Tempy. Hon. S. to Out-patients.
Manchester County Mental Hospital, Prestwich.—Locum Tenens. 8 guineas weekly.
Nottingham, Bagthorpe Institution and Infirmary.—Res. Asst. M.O. at rate of £300.
Plymouth County Borough.—Asst. M.O.H. £750.
Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. S.
Rochester, St. Bartholomew's Hospital.—Third Res. M.O. at rate of £200.
Rochford Hospital.—Asst. Res. M.O. £125.
Royal College of Surgeons of England.—Examiners in Anatomy, Dental Surgery, &c.
Samaritan Free Hospital for Women, Marylebone-road, N.W.—Reg. at rate of £100.
Sheffield Royal Infirmary.—Surg. Reg. £200. H.S. £80. Also Dental S.
Sutton, Surrey, Downs Hospital for Children.—Asst. M.O. £550.
Westmorland, Sanatorium, Meathop, Grange-over-Sands.—Res. Asst. M.O. £350.
Whittingham County Mental Hospital, Preston, Lancs.—Two Tempy. M.O's. Each £7 7s. weekly.
Winchester, Royal Hampshire County Hospital.—H.S. £150.
Winsley Sanatorium, near Bath.—Asst. Res. M.O. £250.
The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointments: Cromer, Norfolk; Higham Ferrers, Northants; Sandy, Beds; Silverton, Devon; Lanchester, Durham; Overton, Flint.

Births, Marriages, and Deaths.

BIRTHS.

Lyster.—On April 4th, at Great Baddow, Essex, the wife of Ronald Guy Lyster, M.B., B.S., of a son.
McMorland.—On April 3rd, at Brookfield, Colyton, Devon, the wife of Dr. J. Bruce McMorland, of a son.

MARRIAGES.

Bridges—Luard.—On March 31st, at St. Leonard's Church, Lexden, Colchester, Major Robert Francis Bridges, R.A.M.C., to Charlotte Lucy Chauncy, second daughter of the late Edward Chauncy Luard, and of Mrs. Luard, of Holly Lodge, Colchester.
Elliott—Richards.—On April 4th, at St. Paul's, Hampstead, London, Charles C. Elliott, D.S.C., M.D., M.R.C.S., of Seaford, Sussex, to Lorna Richards, M.B., Ch.B., second daughter of the late Mr. C. Hooper Richards and Mrs. Richards, of Birmingham.
Rainer—Boulton.—On April 4th, at St. Paul's Church, Herne Hill, S.E. 24, Charles Farrell Rainer, M.R.C.S., L.R.C.P., eldest son of the late Charles Oliver Rainer, of Georgetown, Demerara, British Guiana, and of Mrs. Alice Maud Rainer, Upper Norwood, London, to Kathleen May, widow of the late Raymond Wright Boulton, R.F.A.

DEATHS.

Eager.—On April 8th, at Perryn-road, East Acton, Thomas Cawley Eager, M.R.C.S., L.R.C.P., late of Woking, in his 80th year.
Prichard.—On April 8th, after an operation, Evan Christopher Prichard, M.D., of Horse Fair, Banbury, aged 47.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Berkshire Hospitals.—Princess Mary last week opened a new nurses' home at the Royal Berkshire Hospital, Reading, which will accommodate a staff of 89 nurses. The Royal Berkshire and Associated Hospitals Aid Committee now has a membership of more than 100,000, and last year 57 per cent. of the patients treated at the Reading institution were contributors to the scheme. Of the £19,000 collected in 1924, £12,000 came from the country districts.

Notes, Comments, and Abstracts.

THE DUTIES OF MEDICAL OFFICERS OF HEALTH.

The more important functions, both general and specific, of medical officers of health in England and Wales are summarised in a memorandum[1] just issued from the Ministry of Health. Those to whom it is primarily addressed will for the most part be familiar with its contents, but will appreciate the convenience of possessing a concise pamphlet which amplifies Article 14 of the Sanitary Officers Order, 1922 (*a*), where the duties of the medical officer of health are specified with extreme brevity. An index to the statutes, orders, and regulations relating to the powers and duties of medical officers of health is arranged alphabetically in an appendix, so that the M.O.H. will find no difficulty in gaining further information as to his duties and rights. Doctors in private practice do not always realise how extensive are these duties and rights and occasionally resent as officious interference an investigation into the circumstances of cases of infectious disease or of tuberculosis, or active encouragement of local welfare centres. It is to practitioners, therefore, that we commend the study of this pamphlet.

HEALTH HINTS FOR SCHOOL-CHILDREN.

The Borough of Hornsey is to be congratulated on a useful method of propaganda in regard to the prevention of disease. A little book with the title "Health Hints for School-Children," written by Lr. A. T. Nankivell, the school medical officer, has been distributed in all the public elementary, secondary, and private schools in Hornsey, and gives in clear language hygienic counsel in regard to teeth, dirt and disease, drains, the dust-bin, exercise, fresh air, food values, eyesight and sleep, with notes on the danger of flies and how to seek municipal advice where sanitary house defects or infectious diseases are in question. The illustrations are simple and good, and the lessons, if taken to heart by a school population, would certainly promote the public health.

VENTILATION AND HUMIDIFICATION IN COTTON MILLS IN INDIA.

The subject of ventilation and humidification in cotton mills has been under discussion for many years, as it was found that in most mills the necessity for the employment of artificial humidification has proved a serious obstacle to improvements of conditions. In 1921 the Government of India instituted a special inquiry which was entrusted to Mr. T. Maloney, *M.C.*, A.M.C.T., who was instructed (1) to obtain accurate observations regarding the method of humidification and ventilation employed in cotton mills and their effect on working conditions, and (2) to evolve recommendations designed to effect a marked amelioration in conditions without serious detriment to the industry.

After about 18 months spent in the inquiry Mr. Maloney has presented his report, and his general conclusion was that "while it has not been definitely proved that health is materially affected in every case, it is significant that the physique of the average cotton operative is much lower than that of workers of similar castes and wage-earning capacity in other trades, and that weight decreases after a few months' continuous service." Mr. Maloney suggests the use of the kata-thermometer for measuring the cooling power of the air, and the standard of cooling power as measured by the wet kata cooling power should be 11 (milli-calories per sq. cm.) at head level. Although a considerably higher standard would be advantageous, as a result of his observations Mr. Maloney considers that this standard would prevent danger to health and serious discomfort among the operatives, and generally a vast improvement in existing conditions. In some centres like Madras the proposed standard is already exceeded for most of the year, and little difficulty would be met with in conforming to the standard continuously, but, in other areas, like Ahmedabad and Bombay, the cooling power seldom remains above the standard for the whole day, and often fails to attain it at any time in the course of the day. It is proposed to allow a period of two years to enable them to introduce adaptations and arrangements necessary for producing the required standard of cooling. The report also proposes (*a*) the provision of an adequate number of hygrometers in departments where humidity is likely to be excessive, and (*b*) the maintenance of humidity registers containing records of the wet and dry bulb temperatures. It is further suggested that where steam is used for the purpose of artificial humidification, its introduction should cease when the dry bulb temperature of the room exceeds 85° F. Factory inspectors are to be empowered to insist on the adoption of methods designed to reduce temperature and particularly to place restrictions on the methods of construction in the case of new mills. For existing mills it is suggested that inspectors should be able to insist on white-washing of roofs or of spraying them with water when temperatures are excessive.

---

[1] Memorandum on the Duties of Medical Officers of Health in England and Wales (other than the Medical Officer of Health of the London County Council and Medical Officers of Health of Portand Riparian Sanitary Authorities). 1925. H.M. Stationery Office Pp. 22. 2*d*.

The Government of India are apparently inclined to support the proposals made in Mr. Maloney's report, and it may be anticipated that some, if not all, of the suggestions made will be introduced within the next year or two.

"SCIENCE, CRIME, AND CHRISTIANITY."

UNDER this title a sermon was delivered by Mr. Arthur R. L. Gardner at the Church of St. Martin-in-the-Fields, London, on Jan. 20th, the anniversary of the death of John Howard, the Prison Reformer, who was born in 1790; the Howard League for Penal Reform, 18, Savoy-street, London, W.C. 2, has now published the sermon in pamphlet form (*2d.*). Mr. Gardner outlines the progress of scientific thinking since pre-Victorian days, and recognising the tendency to mental inertia, points out "Our danger in this country . . . is not that Science will be impeded in her advance, but that she will advance in every other country except ours." He believes that the first step in removing the conditions which engender criminality is to inquire into the whole system of established thinking about God and human nature, and he quotes Dr. Hamblin Smith, the medical officer of H.M. Prison at Birmingham, that there are abnormal mental conditions, not yet recognised by the law, which are potent factors in the production of crime. From the standpoint of the Church, the author of the sermon says scientific penal reform means the disappearance of the Puritan doctrine of the State punishment of wickedness and vice and all the untold misery that it has caused. He does not turn away from the question Pilate asked, but gives as the answer, "The mind of Science incarnate on earth, revealing the true mind of God to the world, in order to save it from all the self-inflicted misery of centuries upon centuries of wrong thinking about God and Human Nature."

WILLIAM LYNN, JOHN HUNTER'S FRIEND.

Hunterian orators at the Royal College of Surgeons of England have for many years shown great ingenuity in saying something new about John Hunter, and certainly Sir D'Arcy Power's Oration presented the master in a new way. John Hunter had not before, that we can remember, been presented through the medium of reminiscence, and the circle of his friends and pupils, who survived into the nineteenth century, were singularly dumb. In fact, Jesse Foot's libels are more detailed than their eulogies. That William Lynn should have left no record of Hunter has always seemed surprising. He was one of the chief of Hunter's associates and assisted him in the formation of his museum, but he left no account of his master and our knowledge of himself is fragmentary. At the time of his death in 1837 THE LANCET described only his last day on earth, and the "Dictionary of National Biography" appears silent.

William Lynn was born in 1755, and at the time of his death was almost the last survivor of the personal friends of John Hunter. We are tempted to believe from what little we know of him that he preserved much of the Hunterian manner. Barnard Holt, F.R.C.S., writing in 1861, records a quaint pronunciation used by him. "*Nater*, gentlemen, *Nater* cures the disease," he would exclaim during lectures "in his eccentric way," when referring to the *vis medicatrix naturæ* and the Hunterian belief therein. Can it be that an old pronunciation lingered on here from another and more famous speaker's lips? Lynn was not apparently an illiterate and was not therefore guilty of a Cockneyism. We prefer to think that he remembered a Scotticism. He seems to have been better known as an operator than as an author, but in 1786 he published in elegant enough English a short tract, previously read by him to the Royal Society, entitled "The Singular Case of a Lady who had the Small-pox during Pregnancy; and who communicated the Same Disease to the Fœtus." The pamphlet is based largely on a previous case described by John Hunter. As an operating surgeon Lynn was famous, and we read how in 1796 it was the custom of groups of students from the united hospitals of Guy's and St. Thomas's to visit in turn the other hospitals of London, there to witness the operations of Sir James Earle, William Blizard, and Lynn. Thomas Martin, one of the original 300 Fellows of the Royal College of Surgeons, was among these migratory visitants. He saw Lynn at work at the Westminster Hospital, but his descriptions of these "masterly operations" died with him. Silence settles on the memory of William Lynn till 1837, when THE LANCET informed its readers that he died suddenly whilst getting into his carriage at a quarter to two in the afternoon of June 24th. He had just been calling on a relation near Bloomsbury-square and was returning to his house at Clapham. He was in the best of spirits, "and stated, when allusion was made to the recent decease of his late Majesty [William IV.], that he well recollected the death of George II." (THE LANCET, 1836-37, vol. ii.) His pleasant portrait, reminiscent of Mr. Pickwick, by J. Ward, is still at the Royal College of Surgeons in Lincoln's Inn-fields, but it cannot tell us what the living original knew of his famous friend, John Hunter.

HEALTH CONDITIONS IN BRUNEI.

Mr. E. E. F. Pretty, the British resident in this native State, situated on the north-west coast of Borneo, has issued a report for the year 1923, from which it appears that the death-rate was roughly 40 per mille and the birth-rate 52·4 per mille as far as the figures available show. The total European population at the end of the year was 35, and their health was good. Malaria was less prevalent than in 1922. The percentage of school-children showing splenic enlargement fell from 18·39 to 13·04. The medical officer states, in regard to ankylostomiasis, that the indications received of this disease did not show any great difference from those of the previous year, but until a proper campaign is undertaken, with routine and exhaustive examination, it will be impossible to estimate the prevalence of the infection. It must be borne in mind that the main native population live actually in huts erected over a tidal river, and the dejecta of more than three-quarters of the population are passed straight into the river. There is thus not an urgent necessity to undertake a proper survey of this infection in Brunei. Almost the same remarks apply in regard to amœbic dysentery, of which very few cases are seen. Pulmonary tuberculosis is fairly prevalent in the State, but it is almost impossible to get the natives to come for treatment. Judging from the cases of people suffering from other diseases who are seen by the medical officer, and in whom pulmonary tuberculosis is found on examination, it may be estimated that at least 3 per cent. of the general population are harbouring active tubercle bacilli in their lungs. The total number of vaccinations done in the State was 812, as against 442 in 1922. This increase is due to vaccinations amongst Kedayans who previously had refused to be vaccinated. The Brunei Malays do not like their children to be vaccinated until they are over 1 year old. Vaccination is not at present compulsory. The Brunei native is very conservative in the matter of health and treatment for ill-health. He is extremely reluctant to be seen by a European medical man, and when seen he is still more reluctant to take the treatment prescribed. His prejudice against admission to hospital is so deeply rooted as to make him rather lose his life than enter. This applies in still greater force, if possible, to his female relatives. There is no hospital in Brunei. Those requiring hospital treatment, and willing to submit to it (chiefly Government servants and prisoners), are taken to Labuan Hospital, to which the Brunei Government pays a small annual subscription. The rubber estates almost entirely employ the Brunei Malays as their labourers, and these, as already stated, object to treatment by a European medical man. There is no system of night-soil sanitation in Brunei; even the Asiatic population living on the banks of the river use latrines which are built over the river, and the dejecta are taken away by the tide. There were no epidemics of infectious or contagious disease in 1923. Dr. T. C. A. Claverton, the medical officer at Labuan, acted in the same capacity in Brunei, paying altogether 17 visits of varying duration. He has won the confidence of the natives to a remarkable degree. The Brunei dispensary, in charge of Dresser Leong Ah Ng, treated a total of 2249 patients during the year. The area of the State of Brunei, which was placed under British protection in 1888, is about 4000 square miles, and the population is estimated at about 30,000, chiefly Malays and Borneans. The mean temperature in the shade in 1923 was 80·73° F., and the rainfall, as registered at seven stations, ranged from 99·26 inches to 164·94 inches for the year.

PUBLIC HEALTH IN THE STRAITS SETTLEMENTS.

A REPORT for the year 1923, prepared by the Colonial Secretary, has recently been issued. The colony consists of the island of Singapore (with its dependencies), Penang (including Province Wellesley and the Dindings), Malacca, the Cocos or Keeling Islands, Christmas Island, and Labuan. The estimated population of Singapore is 457,571, of Penang 310,781, and of Malacca 160,886. The crude birth-rate for the year was 30·43, and the crude death-rate 27·80 per mille, the latter being the lowest on record. Deaths from pneumonia were 1710 and from influenza 162. Beri-beri accounted for 904 deaths, as against 1388 and 1299 in 1922 and 1921 respectively. Malaria and tuberculosis were responsible for 3430 and 2683 deaths respectively, fever unclassified for 3064, dysentery for 839, and diarrhœa for 411. There were 18 deaths from cerebro-spinal meningitis, 56 from plague, and 3 from small-pox, but none from cholera. The prevalence of venereal disease in Singapore has given cause for grave anxiety, and a small committee was appointed to consider and report on the question. The report, which was presented in July, disclosed a very disquieting state of affairs, and measures to remedy this are receiving the careful and anxious consideration of Government. The climate of the Settlements varies but little during the year. The mean temperature in Singapore for 1923 was 80·80° F.; in Penang 81·9°; and in Malacca 82·00°. There are no well-marked rainy and dry seasons, the rainfall being pretty equally distributed throughout the year.

THE LATE DR. OSCAR JENNINGS.

It is impossible to get ahead of a catchy statement once it has become widely circulated; we still receive communications referring to a dictum of the late Dr. Oscar Jennings that every fourth doctor is a drug habitué. Oscar Jennings was a clever and eccentric man who lived most of his professional life in New Zealand and Paris, though he died at Ramsgate just after the opening of the war. This accounts for the absence of his name from the Medical Register to-day, which has been noted critically in some of the commentaries upon his words. His statement was, of course, absolute rubbish, but, looking at the connexion in which it was made, it is probable that he, obsessed though he was with the prevalence of morphinism, did not say what he meant to say. In his clientèle in Paris there was a very large proportion of medical men, some neurologists, and most of those interested in occult sciences and folk-lore. Hence it was generally assumed, at the time when he wrote his frequently quoted words, that he was making a thoughtless deduction from the entries in his case-book at a particular moment, when he was struck by the high percentage of medical men among those consulting him as drug addicts. Dr. Jennings's general conclusions on morphinism were not taken altogether seriously though his clinical experience was large, nor was he a scientific neurologist, although he translated into French certain neurological classics and was medical electrician in a Paris hospital. His wide acquaintance in Paris was largely due to his interesting personality, and especially to his energy in recommending the use of the bicycle and tricycle to both sexes as the readiest method of obtaining hygienic exercise at a time, nearly 40 years ago, when cycling was not a part of the daily life of a large proportion of the population.

A REGRETTABLE INEXACTITUDE.

To the Editor of The Lancet.

Sir,—As a member of the London Panel Committee, I hope you will forgive me for protesting, with such restraint of my indignation as I can effect, against the gross inexactitude, and resulting libel, embodied in your principal leading article of April 4th. In the course of that article, rightly criticising the high-handed activity of the Ministry of Health, you—not once, but five times—accuse the Panel Committee for the County of London of having formulated an unjustified charge against one of their fellow practitioners, and as having been rightly condemned therefor by the Inquiry Committee set up to consider the case. The number of the references negatives one's first assumption that a slip of the pen explained the libel. One is therefore driven to the conclusion that the writing of this article was deputed to a member of your staff so unfamiliar with the various statutory bodies concerned with the regulation of medical practice as to be unaware that the Panel Committee and the Insurance Committee for the County of London are two distinct entities, of utterly different composition and utterly differing functions. Needless to say, it is the latter body that alone was concerned in this unfortunate prosecution.

I trust you will—as I am sure you will—give to this correction the same publicity that you gave to the regrettable mis-statement complained of.

I am, Sir, yours faithfully.

63, Harford-street, E., April 8th, 1925. Harry Roberts.

*** The cases referred to in our article have been brought by the Insurance Acts Committee to the notice of the Royal Commission on National Health Insurance, and further comment would be unprofitable at this stage. The Insurance Committee for the County of London was the body which made the representations to the Ministry of Health, when the Inquiry Committee was appointed for an investigation of the circumstances, as stated in our leading article. Dr. Roberts is wrong in assuming that a slip of the pen does not account for a description of the situation which must have been perfectly clear to most of our readers. It should have been explained that the connexion of the Panel Committee could be only slight, through members of that Committee finding a place on the Medical Service Subcommittee of the Insurance Committee. We are sorry to have to endorse Dr. Roberts's title that we have committed "a regrettable inexactitude," but when he uses the word libel, we cannot see that any individuals have been accused of anything wrong; the whole purpose of the article was to show that a situation had arisen that merited Departmental attention.

The following is a paragraph additional to the Memorandum of Evidence to be submitted by the British Medical Association to the Royal Commission; a digest of the Memorandum will be found in our issue of Jan. 10th, p. 95.

"There have recently been a number of cases in which the action of the Ministry of Health in imposing penalties on practitioners has appeared to the Association to be of an inexplicable character, and has given rise in the minds of many practitioners to a feeling of injustice, or even of a suspicion of vindictiveness. The Association recognises the administrative duties of the Ministry in this connexion, and is very anxious to foster in the profession a feeling of confidence in the exercise by the Ministry of its judicial or quasi-judicial functions associated therewith. When, however, agreements with the profession have been reached with regard to the machinery and procedure by which decisions shall be arrived at, it is exceedingly disquieting to find that, though the machinery is used and the procedure followed, there are cases in which there seems little or no relationship between the decisions of the Ministry and the reports or recommendations of the bodies on which action is supposed to depend."—Ed. L.

A DANGEROUS DEVICE.

A correspondent sends us a specimen of a sponge cut into the shape of a cylinder with rounded ends, approximately 2½ in. long and ¾ in. in diameter, which is designed for insertion into the vagina during menstruation, as a substitute for the use of a sanitary towel. It is enclosed in a net and one end is covered by a rubber cap. The instructions for use include a "note for unmarried women" wherein they are informed "when the presence of the hymen is probable, the insertion of a sponge should not be attempted except under qualified advice." The disadvantages and dangers of this device will be apparent to our readers and we call attention to it only because the (unsupported) statement is made that it has been approved by doctors.

CHRONIC ULCERATIVE STOMATITIS.

To the Editor of The Lancet.

Sir,—May I, through the medium of your columns, seek the experience of others in the prevention of chronic ulcerative stomatitis. My patient, a moderately active young man of temperate habits, has been the victim of ulcers of his tongue, cheeks, and gums during the past five years. He had attacks of indigestion formerly, but has been free from these now for some considerable time. The ulcers continue to appear one, to three, or four, at a time for a period of several weeks; he is then free for a while, only for another crop to appear later. The patient keeps to a wholesome but not a strict dietary, and although the ulcers disappear rapidly under applications of sanitas, potassium chlorate, and silver nitrate, I am unable to prevent their recurrence.

I am, Sir, yours faithfully,

Herne Hill, S.E., April 7th, 1925. Guy Meadows.

ROYAL VICTORIA HOSPITAL, BELFAST: ANNUAL REPORT.

The annual report for 1924 showed a large increase in the volume of work in all departments. The financial statement showed an income of £53,914 and an expenditure of £54,424. The subscriptions from the working classes, which are one of the principal sources of income of the hospital, were fully maintained in spite of the existing industrial depression, and amounted to £20,000. The new dental department continues to grow and there are now 25 dental students. Details are given regarding the extensions of the hospital now in course of erection. These will include 80 additional beds, a new block for nurses, additions to the out-patient departments, larger accommodation for the eye, ear, and throat department, the venereal department, the dental department, and the X ray department, three new operating theatres, and a new mortuary. These extensions have been in progress for nearly two years, and it is expected that they will be completed in a few months. They will make a substantial addition to the resources of the hospital, the pressure upon whose accommodation is severe and always steadily increasing. The waiting-list exceeds 300. The total cost of these extensions is estimated at £120,000.

EDEN'S MIDWIFERY by HOLLAND

Being the 6th Edition of A Manual of Midwifery

By **T. W. EDEN**, M.D., and **EARDLEY HOLLAND**, M.D., F.R.C.P., F.R.C.S., Obstetric and Gynæcological Surgeon, and Lecturer on Obstetrics and Gynæcology, London Hospital.
393 Text-Figures, 7 Plates (4 in Colour). **21s.** net, postage 9d.

10s. 6d. net, postage 5d.
HALE-WHITE, 18th Ed.
Materia Medica

73 Illustrations. **24s.** net, postage 9d.
CUSHNY, 8th Ed.
Pharmacology

At the present time these two books are not only the most celebrated on their subjects, but they are also among the best sellers in the field of medical literature throughout the English-speaking world.

London: J. & A. CHURCHILL, 7, Great Marlborough Street, W.1.

Messrs. LONGMANS & CO.'S LIST.

THE ACTION AND USES IN MEDICINE OF DIGITALIS AND ITS ALLIES.

By **ARTHUR R. CUSHNY,** M.A., M.D., LL.D., F.R.S., Professor of Pharmacology in the University of Edinburgh.
With Illustrations. 8vo. **18s.** net.

An account of the pharmacology of the digitalis group which, it is hoped, may prove of service to the physician in practice in his treatment of heart disease and may afford a foothold from which further advance may be made in the science and art of medicine.

PRINCIPLES OF GENERAL PHYSIOLOGY.

By **Sir W. M. BAYLISS,** M.A., D.Sc., LL.D., F.R.S., late Professor of General Physiology in University College, London.
FOURTH EDITION. With Illustrations. 8vo. **28s.** net.

This edition has been prepared by a Committee of the Author's friends, under the general direction of Professor A. V. Hill, F.R.S. The Committee consists of N. K. Adam, E. D. Adrian, G. V. Anrep, J. Barcroft, F. F. Blackman, A. E. Boycott, R. K. Cannan, A. J. Clark, H. H. Dale, J. C. Drummond, C. Lovatt Evans, W. O. Fenn, H. S. Gasser, J. Gray, D. T. Harris, H. Hartridge, D. C. Henry, A. V. Hill, T. Lewis, E. K. Rideal, A. D. Ritchie, Ruth Skelton, E. H. Starling.

A photograph of the late Sir William Bayliss working in his laboratory, which was taken about four years ago by Professor H. S. Raper, has been added as a frontispiece.

AN INTRODUCTION TO GENERAL PHYSIOLOGY.

WITH PRACTICAL EXERCISES. By **Sir W. M. BAYLISS,** M.A., M.D., F.R.S.
With Diagrams. 8vo. **7s. 6d.** net.

ESSENTIALS OF PHYSIOLOGY.

By **F. A. BAINBRIDGE,** M.A., M.D., F.R.S., and **J. ACWORTH MENZIES**, M.A., M.D.
FOURTH EDITION. With 194 Illustrations, some of which are Coloured. 8vo. **14s.** net.

THE PHYSIOLOGY OF REPRODUCTION.

By **FRANCIS H. A. MARSHALL,** Sc.D.(Camb.), D.Sc.(Edin.), F.R.S.
SECOND AND REVISED EDITION. With Illustrations. 8vo. **36s.** net.

PHYSICAL CHEMISTRY FOR STUDENTS OF MEDICINE.

By **ALEXANDER FINDLAY,** M.A., D.Sc., F.I.C., Professor of Chemistry, University of Aberdeen.
With 39 Figures. 8vo. **8s. 6d.** net.

The great advances which have been made in recent years through the application of the methods and teachings of physical chemistry to the study of physiology, bacteriology, and other branches of biological science underlying medical practice have made it imperative for the student of medicine to acquire some knowledge of that branch of chemistry. In the present volume, those parts of physical chemistry which have found important applications in the medical sciences are discussed in an elementary manner, but also in sufficient detail to enable the student to read with profit larger and more specialised works.

X-RAYS.

By **G. W. C. KAYE,** O.B.E., M.A., D.Sc., F.Inst.P., Superintendent of the Physics Department, the National Physical Laboratory.
FOURTH EDITION. With Plates, Diagrams and Tables. 8vo. **16s.** net.

"To all who have to use or deal in any way with the X-Rays we recommend the purchase of Dr. G. W. C. Kaye's admirable text-book on the subject. The reader will find in it a clear and intelligible account of a most complicated subject, presented without any excessive use of mathematical formulæ, yet thorough and complete."—BRITISH MEDICAL JOURNAL.

GRAY'S ANATOMY (Descriptive and Applied).

TWENTY-SECOND EDITION. Edited by **ROBERT HOWDEN,** M.A., M.B., D.Sc., Professor of Anatomy in the University of Durham. With **Notes on Applied Anatomy.** Revised by **JOHN CLAY,** K.H.S., C.B.E., M.B., F.R.C.S., and **JAMES DUNLOP LICKLEY,** M.D.
With 1265 Illustrations, of which 587 are Coloured. 8vo. **42s.** net.

QUAIN'S ELEMENTS OF ANATOMY.

VOLUME IV. PART 2. MYOLOGY.
By **T. H. BRYCE,** M.A., M.D., F.R.S., Professor of Anatomy, University of Glasgow.
With Sections on the Actions of Muscles by **THOMAS WALMSLEY,** M.D., Professor of Anatomy, Queen's University of Belfast.
With 53 Coloured Plates and other Illustrations. Royal 8vo. **25s.** net.

A MANUAL OF PRACTICAL ANATOMY:

A Guide to the Dissection of the Human Body.

By **THOMAS WALMSLEY,** M.D., Professor of Anatomy, Queen's University of Belfast.
With a Preface by **THOMAS H. BRYCE,** M.A., M.D., F.R.S.
In Three Parts. 8vo. Part I.—The Upper and Lower Limbs. **9s.** net.
Part II.—The Thorax and Abdomen. **10s. 6d.** net. Part III.—The Head and Neck. **10s. 6d.** net.

LONGMANS, GREEN & CO., 39, Paternoster Row, London, E.C.4

Croonian Lectures

ON THE

RÔLE OF FATS IN VITAL PHENOMENA.

By J. B. LEATHES, F.R.C.P. Lond., F.R.S.,
PROFESSOR OF PHYSIOLOGY, UNIVERSITY OF SHEFFIELD.

LECTURE II.*

The attempts to make intelligible the rôle of fats in the life of the cell which I tried to review in Lecture I. fail to satisfy the needs, and we have to search for further knowledge of the physical behaviour of fatty substances insoluble in water before we can form ideas that approach the truth. How near we may hope to get with available data we can only determine after taking count of certain facts that have not yet been generally incorporated in the scheme of biological studies.

Orientation of Molecules in Surface Films.

The most important and most promising group of facts bearing on the behaviour of fatty substances in the presence of water is that which points to the orientation of molecules in a surface. It may often be convenient for the sake of argument to consider molecules as if they were spherical, but the whole of chemistry is built upon theories of the disposition in space of the parts of a molecule in relation to one another, theories which receive confirmation from so many sides that they must in the main correspond to the truth, so that to suppose that molecules really are spherical amounts to ignoring most of what chemistry has taught. Molecules can neither be spherical, nor can all parts of them be indistinguishable from each other.

And though it may not be possible to say positively what the shape and pattern in space of many or even with certainty any molecules may be, it is quite certain that a molecule of palmitic acid is not spherical, and must be of an elongated form with at one end characteristics that are entirely different from those at the other end. It is equally certain that protein molecules are not spherical, but while no one can yet present a picture of the spatial pattern of a protein molecule, or follow into three dimensions the intricacies of its stereochemical structure—the very thought of it induces giddiness—the plan of the structure of a simple fatty acid like palmitic acid is necessarily simple, elongated, and with two distinguishable ends.

That the parts of which a molecule is composed determine the position also which it assumes in relation to other molecules of the same kind in crystals has been proved by the measurements of X ray spectra by Bragg; each atom in a crystal takes up a definite position in space in relation not only to the other atoms of the same molecule, but to those of the molecules in its neighbourhood. Harkins [1] and Langmuir [2] have pointed to a similar conclusion that in the surface presented by one liquid to another with which it is immiscible there may tend to be an ordered juxtaposition of the molecules so that some one and the same particular part of each molecule of the same kind is directed towards the mass of molecules of the other kind. This is merely a part of the ideas they have brought forward, but it is the part with which we are immediately concerned.

Measurements Obtained by Observation of Films.

There are some beautiful measurements that afford the strongest proof of this conception in the work of N. K. Adam.[3] He has improved upon the methods employed by Langmuir, and learnt much from the still earlier work of Hardy. He measures the area occupied by a film composed of a fatty acid, an ester of a fatty acid, or some other derivative containing the long hydrocarbon chain, spread out on a water surface. The water is contained in a metal trough, the edges of which have been painted with paraffin wax, so that the water will not creep over them; and the surface of the water is cleaned so as to remove all contaminating foreign matter by sweeping across it a similarly paraffined bar of glass. On to the freshly cleaned surface a known weight, three or four small drops, of a dilute solution of the fatty acid in benzene is placed. The benzene evaporates, leaving a known number of molecules of the fatty acid on the surface, occupying an area that can be measured by pushing from one end of the trough a paraffined glass bar until it presses the film against a paraffined float stretching across the other end of the trough. The pressure exerted by the film on this float is detected by the movement of the float, and its amount measured by a balance, one arm of which is acted on by the float, while the other arm carries a pan for weights. Accurately adjusted jets of air prevent the film from being driven through the narrow gaps between the ends of the float and the sides of the trough. In this way the area occupied by the film can be measured, and the compressing force to which it is exposed also.

It is found that the area occupied by the film, when the molecules are packed close by the compressing force, corresponds to an area per molecule of 21 sq. Å (Å $= 10^{-8}$ cm.), this area being the same for all saturated fatty acids that give films, and also, it may be noted, for many other compounds in which a similar chain of carbon atoms is the common feature. From the density of the solid acid in bulk the volume occupied by a molecule of the acid in the solid material can be calculated. Supposing that the molecules in the film are actually as close packed as they are in the solid acid, and occupy, therefore, the same volume, if this volume be divided by the area in the film occupied by the molecule, the third dimension of the molecule is obtained, and in the case of palmitic acid the value for this dimension is nearly 24 Å. The area of 21 sq. Å would be given by a square with sides of 4·7 Å, so that a molecule of palmitic acid in the film would occupy in that case a volume with one dimension about five times as great as the others; the longer dimension is vertical to the water, one end of the molecule being on the surface of the water and the other directed away from it. At one end of the molecule is the acid carboxyl group, at the other the terminal methyl group of the paraffin chain. The end directed to the water must be that at which the carboxyl group is situated, for the reason, among others, that if for this group a methyl group be substituted, so that both ends are alike, neither end adheres to the water. The paraffin hexadecane, which differs from palmitic acid only at this point and in this way, does not form a film, there being no part of the molecule that is capable of binding it to the water; it is paraffin from end to end. The molecules remain heaped up and clinging together.

The same conclusion as to the orientation of molecules in surface films such as these had been arrived at before by Langmuir and by Harkins. The proof given by Adam's measurements for a larger number of substances is complete. It follows from this that substances which are insoluble in water may, nevertheless, not be indifferent to it. A molecule of a fatty acid such as palmitic acid, so far as its hydrocarbon chain is concerned, in regard, that is, to 15 out of the 16 carbon atoms of which it is composed, retains the characteristics of the paraffin hexadecane, which water will not wet. The terminal carbon atom in the carboxyl group has affinities for water which, though not able to overcome this paraffin property as it can in an acid with a shorter paraffin chain, in some measure even in one containing as many as 12 carbon atoms in all, is nevertheless able to exert a profound influence on the behaviour of the molecule in relation to water. Such molecules might be compared to the quills used for floats in fishing which have one end weighted. With quills of the same thickness, but different lengths, it would be found on attaching a certain weight to one end, the same weight to all, that those of less than a certain length would be totally immersed in the water, those of more than that length would float vertically on its surface; whereas the same quills without the weights would all alike float lying horizontally on it. Paraffins are all immiscible with and lighter than water; the acids derived from them have with increasing length of hydrocarbon chain diminishing solubility, but still sum up to the one with 12 carbon atoms; those of higher molecular weight than this are not in any degree soluble; they float in a vertical position on the surface held upright by a force exerted on the carboxyl group by the water molecules.

---

* Lecture I. appeared in THE LANCET last week. Lectures III. and IV. will appear in subsequent issues.

The simile obviously cannot be pressed. For one thing, the fatty acid molecules are in consequence of strong attractions exerted by the paraffin chains on each other made to cohere to one another; and for another, they must be supposed to be in a state of kinetic activity, varying in amplitude according to whether the film resembles a solid, liquid, or gas. This molecular agitation, however, is not able to disturb the influences which determine what might be called their posture, the force acting between the water and one end of the molecule on the one hand, and that acting between the rest of the molecule and the corresponding parts of its neighbours, which, like it, are paraffin and incapable of affinity to water or anything aqueous.

The forces exerted by the paraffin chains on each other cause the molecules to cohere in continuity; the forces exerted by the water on the carboxyl group cause the molecules to spread on the surface, and limits their continuity to one in two dimensions, in the sense that the film formed is one molecule thick, with that part of each which the water can bind adherent to the water, and that part directed away from the water which the water will not wet. In a paraffin such as hexadecane there is no part of the molecule which the water can wet, and consequently the molecules cohere in three dimensions, not only in two; no film is formed, and the paraffin does not spread over the water.

CHEMICAL PROPERTIES IN RELATION TO PHYSICAL BEHAVIOUR.

There is here a point in the behaviour of fatty acids and their esters that has hitherto not been taken into account by cytologists. Chemical properties are significant not only because of the chemical reactions which they make possible, but also because they determine the positions taken up by molecules in relation to one another, their physical behaviour. Oil does not mix with water, nor does any chemical reaction take place between them on any detectable scale at the ordinary temperature. But there are conditions in which the molecules of oil in contact with water are proved to range up in a definite formation. This ordered juxtaposition of molecules at an interface cannot be overlooked in the attempt to arrive at some intelligible conception of the structural relationships of the components of cell substance.

Another point that Adam has brought out is this: the physical properties of film-forming substances are quite different in the films from those that the same substances exhibit in bulk. Palmitic acid in bulk is a solid up to the temperature of 62·6° C.; in a film on water, if the pH is 5 or less it is liquid at the ordinary temperature of the air. The solidity or fluidity of the film in these experiments is judged by the behaviour of motes floating in it. When the film is solid these are stationary; when it is fluid they move about continually in any direction. A sufficient compressing force can cause a film of palmitic acid to solidify at the room temperature; a force, for instance, of the order of 50 atmospheres may do so, though this does not always occur, and the conditions determining the change have not been exactly defined. Liquid films are similarly obtained with other substances at temperatures far below their melting-point. Moreover, at a certain temperature, in the case of palmitic acid between about 20° and 32°, the compression remaining the same, the film undergoes a change which results in its area being increased by as much as 60 or 70 per cent., and then with a further rise of temperature expanding gradually and uniformly at a much slower rate. Other acids in the same series of lower molecular weight, though still insoluble, give films that are expanded at the ordinary temperature, as does also oleic acid, which even in bulk is of course liquid at still lower temperatures. Such expanded films behave, therefore, in many respects as if they were in a gaseous state.

The physical properties, then, of film-forming substances are quite different in the films from those that the same substances exhibit in bulk. Palmitic acid, which in bulk melts near 63° C. in the film, is liquid at the room temperature, and passes, by a transition reminding one of the passage of a liquid into a gas, into a condition more like that of a gas than a liquid at a temperature 30° below its true melting point. To account for these extraordinary phenomena there would appear to be two conditions that obtain in the film, and not when the substance is in bulk. In the first place molecules are in a single layer, there are no other molecules of their own kind beyond the surface film, no other paraffin chains to enhance the cohesive forces that their own paraffin chains exert on each other. If there were, the resultant of their attractions would act as a force at right angles to the surface and directed upwards from it, which would steady them and impede the freedom of their movements. Without this they are as boats without ballast, much more sensitive to the buffeting to which they are exposed. And then, secondly, in the film they are engaged at one end by the water; so far as that end is concerned it is soluble in the water, it shares so freely in the agitation of the water molecules under kinetic activity that the whole molecule is thrown into a state of kinetic agitation which it would not experience otherwise till its temperature had risen much higher than that observed in its environment. Liquefaction and vaporisation are incident to degrees of kinetic activity. When a solid substance liquefies we say its temperature has risen; it has really shared in the rise of temperature of its environment; and that means merely that kinetic activity has been imparted to it. Some of the kinetic activity necessary to make a monomolecular film of palmitic acid liquefy is not derived from the temperature of its surroundings, but appears to be due to the fact that the carboxyl group is in a sense soluble in the water.

When a substance passes from the liquid state to the gaseous state the distance between the molecules is greatly increased, far more even than the remarkable increase in the distance between the molecules in a film when it passes from the condensed to the expanded state. In an expanded film matter can be observed and studied in a state different from any state in which matter has previously been studied. It may be just to speak and think of it as a gas in two dimensions instead of three. But there is the difficulty about the distance between the molecules, and in any case it is hard to conceive of a gas confined in this way with its molecules moored to the water surface like captive balloons. Perhaps something similar exists in a film of adsorbed gas, where the molecules are known to be much closer together than those of the gas free in three dimensions.

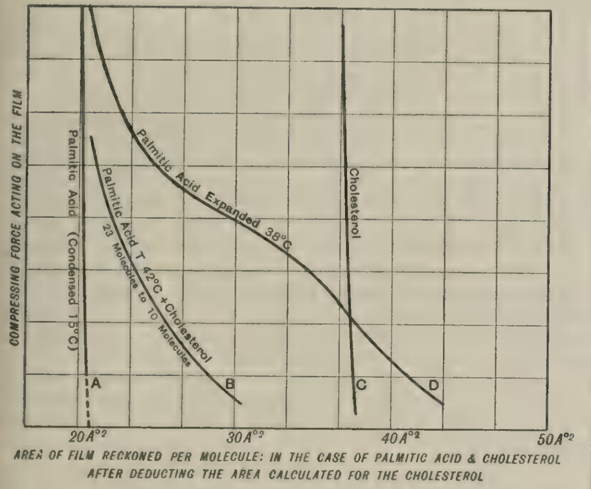
If the substances which are concerned in the formation of the lipoid membrane behave similarly in the surfaces where their molecules, characterised by the long paraffin chains of fatty acid radicals, are confronted by the aqueous solutions of the cell, it is clear that the physical conceptions that cytologists bring to the study of cells must be amplified.

BEHAVIOUR OF LIPOIDS IN SURFACE FILMS.

With Mr. Adam's help I have employed his methods for studying the behaviour of some of these substances in thin films on water. Two preparations of lecithine made by Levene's method from egg yolk, and a valuable preparation made and analysed at the Rockefeller Institute which Dr. Levene was so good as to give me, were found to form films on water which had, speaking generally, the same characteristics as those found by

Adam for the fatty acids and many other substances which he examined. The area occupied by a fatty acid chain, whether in a molecule of fatty acid or of its ethyl ester or triglyceride, is in a condensed film 21 sq. Å (Fig. 1, A). In an expanded film of palmitic acid, under a certain standard compression, this area is 42 or more according to the temperature (Fig. 1, D). At room temperature the area occupied by each of the two fatty acid chains in lecithine was 54 and 58 in the case of my two preparations, and 56·6 (Fig. 2, D) in that of Levene's lecithine proved by analysis to be pure, and at the lowest temperature at which it was measured, 4·5° C., 52·6. The curve of diminishing area with increasing compression traced up to a compressing force of about 60 atmospheres, even at this temperature, showed no signs of the film condensing. It is not possible, therefore, under the conditions of these experiments, to obtain a film of lecithine in a state in which the fatty acid chains are packed close together. The figures seem to indicate, as might be expected, that the glyceryl cholyl phosphoric acid, which links the two fatty acid chains in lecithine, occupies a considerably greater space than the two carboxyls of two fatty acid molecules, prevents the two paraffin chains from coming as close as they otherwise would, and so diminishes the cohesive force that these chains exert upon each other.

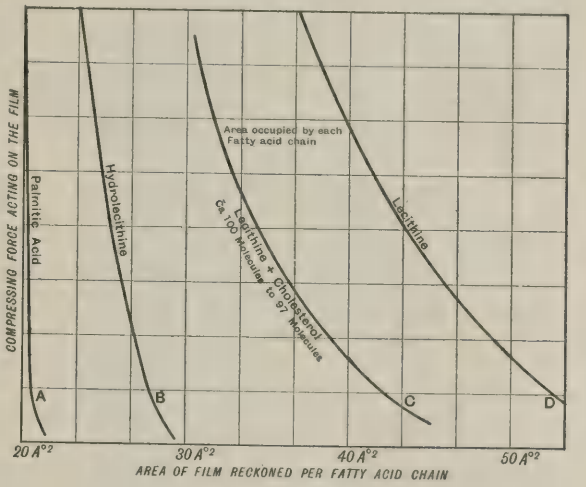
FIG 1.



A preparation of pure hydro-lecithine, which also I owe to Dr. Levene's generosity, was found to give not an expanded film but a condensed one; in this, at the standard compression, the area occupied by each fatty acid chain was 28 (Fig. 2, B), and even under the very high compression that films of this substance withstand of the order of 200 atmospheres, the area was barely as small as that for the same chain in a fatty acid molecule in a film on water at a fortieth of this compression. It is safe to say, then, that the large polar group in lecithine prevents close packing of the fatty chains, and so diminishes the tenacity with which these chains will cohere to each other, at the same time widening the intervals between them through which foreign molecules may pass. For, incidentally it may be said, molecules do pass between the paraffin chains even of a condensed fatty acid film. Through such a film water was shown to evaporate with a considerable velocity. An expanded film must give greater facilities for this to occur, and a lecithine film still more.

The behaviour of cholesterol and its esters was also studied in this way. Seeing that the chemical constitution of cholesterol is still not yet determined in all particulars, the measurements cannot furnish as clear a picture of the structure of the film. Cholesterol prepared with every precaution from gall-stones, recrystallised several times, faultless in appearance, and with the correct melting-point, was heated to remove water of crystallisation, several solutions were made, and many films of each measured. The mean area occupied by the molecule at the standard compression force was 38·3 sq. Å (Fig. 1, C). The compressibility is small, as under 20 times this compression force the area was reduced only about 3 per cent. This suggests that the molecules must be almost as closely packed in the film as in the substance in bulk; but since the successive layers in that condition might interlock with each other, it is not possible to assume that the specific gravity of the substance in a monomolecular film is the same as that which it has in bulk. If, however, it is, the third dimension of the molecule, the thickness of the film, was 16 Å, and the compression force required to reduce its area by 3 per cent. was about 170 atmospheres; the vertical length of the molecule would be a little less than three times its breadth. Its molecular area seems to be the same on dilute acids as it is on water.

FIG. 2.



Cholesterol is no more soluble in water than the higher fatty acids, and it is not without interest that it should form films like these, though with the imperfect knowledge that we have of its chemical constitution it is impossible to say what the grouping is that binds it to the water surface until some of the derivatives that can be made from it have been studied. Certain peculiarities observed in its own behaviour also need further investigation, and may prove of interest.

Cholesteryl palmitate, made from it with palmityl chloride, appears not to give a real film. The area covered by one solution at standard compression varied considerably from 18·6 to 22·7 per molecule, and averaged 20·3; with another solution it averaged 19·0, but the film was visibly solid and not uniform; the molecular area indicated by the measurements appear impossibly small. The only thing to be learnt from this is that the esterification of cholesterol with palmitic acid prevents both these substances from behaving in their characteristic way, and this fact points to the alcoholic hydroxyl in cholesterol as being the group which fixes it to the water. Other esters of cholesterol have not yet been studied.

INFLUENCE OF CHOLESTEROL ON BEHAVIOUR OF LECITHINE IN FILMS.

But in view of many facts with regard to the physiological influence of cholesterol in modifying the behaviour of lecithine, it was interesting to study the effect that cholesterol had on films of lecithine when the solution used for making the film contained both substances. And also it was interesting to see whether cholesterol had any effect on simple fatty acids under such conditions. The method used was to prepare solutions containing the fatty acids and cholesterol, both of course in known suitable amounts, and after measuring the area of the films under different compression forces to reckon what part of this area would be accounted for by the amount of cholesterol put on, deduct this amount from the area of the film, and compare the area left for each molecule of fatty acid to occupy with that which it would have occupied had the cholesterol not been present. In a word, in every case there was recognisable a tendency for this area to be diminished. Even with palmitic acid at ordinary temperature on dilute acid, when, as Adam has shown, the carboxyl groups appear to be in contact, but not the paraffin chains, until the compressing force reaches more than a certain value, the fatty acid molecules in the presence of cholesterol are closer together than they otherwise would be at these lower pressures. With acids that give expanded films, tridecylic acid at the room temperature and palmitic at temperatures between 31 and 40, for instance (Fig. 1, B and D), the effect is much more striking, the area being reduced, though the effect is not so pronounced as it is with expanded fatty acid films.

This effect, the extent of which the curves shown will make clear, is difficult, of course, to interpret, so long as the chemical constitution of cholesterol remains obscure; but the fact that it is observed with fatty acids even more than with lecithine, though still observable with this (Fig. 2, C and D), tempts one to suppose that the action is between the cholesterol and the paraffin chains rather than the complex glyceryl cholyl phosphoric acid, and therefore is again a change in physical behaviour, an alteration in the force of cohesion between these chains, that depends upon chemical characteristics not capable of resulting in actual chemical union in the ordinary sense.

These are the points that this method of investigating these substances has so far brought out. There is obviously much need for further investigation in order to get the definition clear, and it is to me at least obvious that the work which Adam is doing is on the very foundations of physiology, though not of physiology alone.

Hunterian Lecture

ON

REGIONAL ANÆSTHESIA.

Delivered at the Royal College of Surgeons of England on Feb. 13th, 1925,

BY STANFORD CADE, F.R.C.S. ENG.,
ASSISTANT SURGEON, WESTMINSTER HOSPITAL
(*and from the Physiological Laboratory, King's College*).

WITH regional anæsthesia is added to the armamentarium of the surgeon a new weapon by means of which the safety and comfort of the patient are appreciably increased. As the method is based solely upon accurate anatomical knowledge and sound interpretation of physiological phenomena it is perhaps not unworthy to associate this lecture with Hunter's name.

Definition.—By regional anæsthesia is meant abolition of sensation of pain in a definite part of the body by the action of a non-volatile anæsthetic solution introduced in the neighbourhood of the nerves supplying that part.

HISTORY.

The method was originated by Hugo Sellheim[1] in his experimental work on abdominal surgery. It was first published in 1905. Six years later, in 1911, Lawen[2] injected the posterior roots from the ninth dorsal to the third lumbar for a nephrectomy in an old and debilitated patient suffering from emphysema, chronic bronchitis, and arterio-sclerosis. He was the first to introduce the term conduction paravertebral anæsthesia. In 1912 Finsterer, who took up this method, published his results,[3] and a little later Kappis [4, 5]; the latter, after employing the method during a period of ten years, reported in 1922 80 operations on the kidney by this method. By 1916 Ziegel,[6] who extended regional anæsthesia to abdominal as well as renal operations, published a report of 600 cases. By 1919 he had performed 2000 operations under paravertebral conduction anæsthesia.[7] Others followed, in Germany, Braun and Hartel,[8] who called attention to some important points. In France Pauchet,[9] with the assistance of Labat, Sourdat, Laboure, and Laborde, extended the method to all regions of the body. In 1917 Wendling[10] in Thèse de Basle described a method of infiltrating the solar plexus with an anæsthetic solution. This extended the use of regional anæsthesia from the peripheral to the sympathetic nervous system. The method of anæsthetising the solar plexus described by Wendling, the anterior route, was elaborated by Kappis and by Naegeli,[11] who in 1919 published 18 cases. In 1920 Labat[12] described the method of inducing splanchnic analgesia by the posterior route. In America, Allen, Labat,[13] Lawsley and Pugh[14] popularised the method. In this country Mr. O. S. Hillman and Dr. R. E. Apperly reported three months ago 48 and 43 cases of splanchnic analgesia.[15] As it is employed to-day, regional anæsthesia comprises the infiltration of peripheral nerves either at their exit from the intervertebral foramina or more distally, combined, in the cases of abdominal surgery, with the anæsthetisation of the splanchnic nerves and the semilunar ganglia.

DRUGS.

The anæsthetic employed is novocaine. It is six to ten times less toxic than cocaine. In the strength of ½ per cent. solution large quantities can be given with safety if certain precautions are taken. As its melting-point is 156° C. it can be sterilised in an autoclave. It is soluble in water and saline solutions. To avoid all possibility of overdose, 1·5 g. of novocaine powder, sterilised in a sealed glass ampoule, are dissolved in 300 c.cm. of sterile normal saline. The toxicity is so low that the whole amount can be safely given to one patient. It produces no local irritation or infiltration and so is absorbed painlessly. The Board of Trustees of the American Medical Association, in their report[16] on an extensive survey to study the occurrence of accidents arising out of the use of local anæsthetics, quote only one death due to novocaine. The use of adrenalin is not advisable, neither is it necessary. The injections should be in the vicinity of a nerve, not endoneural. If a nerve is bathed in a solution of novocaine the inevitable result is anæsthesia. The anæsthesia lasts two hours or more. Anæsthesia to pain is complete, touch is not entirely abolished, pressure sense is not lost, and this must be explained to the patient, as otherwise the sensation of pressure may be interpreted as pain. Motor power is not affected, but voluntary movements are irregular and weak owing to sensory disturbance and loss of muscular tone; this latter is a great advantage as it produces excellent relaxation, unsurpassed by that obtained by the deepest narcosis anæsthesia. The preliminary use of narcotics is useful in most patients. Morphine and scopolamine in the usual doses are given half an hour before the induction of anæsthesia, and can be repeated before the operation is commenced.

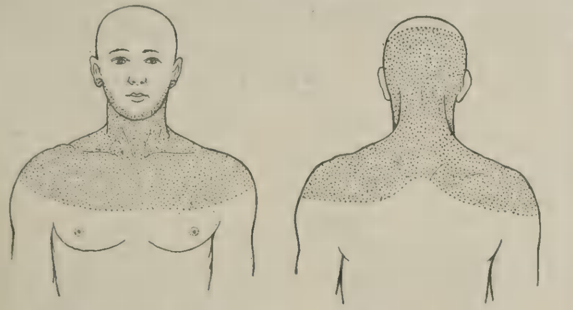
INSTRUMENTS.

The syringe employed is of the record pattern, has a glass barrel of 22 c.cm. capacity, graduated up to 20 c.cm., so leaving a space for preliminary aspiration. Aspiration is absolutely essential, as intravenous injection of novocaine will produce cessation of respiration; this is instantaneous and may last several hours and may kill the patient. Needles of various length are used, the smallest for the formation of dermal wheals, so rendering further punctures painless. Paravertebral anæsthesia can be divided in three groups: cervical, dorsal, and lumbar.

CERVICAL PARAVERTEBRAL ANÆSTHESIA.

The sensory nerve-supply to the neck is derived from the second, third, and fourth cervical nerves, mostly from the anterior primary divisions. Each nerve, after emerging from the intervertebral foramen, is joined by a grey ramus communicans from the superior cervical sympathetic ganglion, and divides at the tip of the transverse process so as to form three loops of the cervical plexus lying under cover of the sterno-mastoid muscle. From these loops branches of distribution arise. The cutaneous branches form the sensory supply to the head, neck, and shoulders. The nerves concerned are six in number. They appear at the posterior border of the sterno-mastoid muscle: two are distributed upwards, the great auricular and the small occipital; one runs forwards, the transverse cervical; and three pursue a downward course, the three descending cervical nerves. Of the posterior primary division the second cervical gives off the great occipital nerve, which forms the chief cutaneous supply of the back part of the scalp. Hence by blocking the second, third, and fourth cervical nerves close to the intervertebral foramina an extensive area of anæsthesia is obtained, extending in front from the margin of the lower jaw to the level of the nipples and behind from the occipital area to the shoulders. (Fig. 1.)

FIG. 1.



Area of anæsthesia after bilateral cervical paravertebral block (C_2, C_3, C_4).

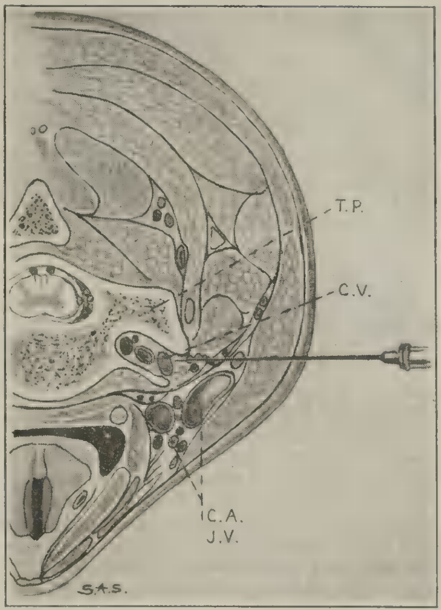
Cutaneous anæsthesia is complete, and manipulation of the blood-vessels, lymphatic glands, muscles, fasciæ, and the thyroid gland is painless.

Technique.—The nearest and safest approach to the second, third, and fourth cervical nerves is from the lateral aspect of the neck. The transverse processes of the cervical vertebræ are identified by palpation and the following points used as landmarks: The upper border of the thyroid cartilage is at the level of the transverse process of the fifth cervical vertebra; one finger's breadth below the tip of the mastoid process marks the level of the transverse process of the third cervical vertebra; this corresponds to the angle of the jaw. The head is turned to the opposite side and these two points marked by raising two cutaneous wheals. The vascular bundle is displaced inwards and a needle 6 cm. long inserted transversely through each wheal till the desired transverse process is reached (Fig. 2). After preliminary aspiration 5 c.cm. of 1 per cent. novocaine is injected for each nerve. The third and fourth nerves are injected through the lower wheal, the second through the upper one. In a short neck one wheal can serve for all three nerves. Twenty c.cm. of ½ per cent. solution is next distributed along the posterior margin of the sterno-mastoid muscle. Anæsthesia is established at once and lasts for two hours. Bilateral cervical block can be induced with ½ g. of novocaine. Paresis of the diaphragm, even if it occurs, is harmless. The most extensive operations in the neck have been performed under cervical paravertebral anæsthesia.

DORSAL PARAVERTEBRAL ANÆSTHESIA.

The induction of the dorsal paravertebral anæsthesia is the most delicate of all regional methods. It requires constant practice, and to be successful the relation of the nerves to the surrounding bony structures must be visualised. Each nerve is formed in the neighbourhood of the intervertebral foramen by the junction of the anterior and posterior roots and at once divides into an anterior and posterior primary divisions; from the anterior primary division of all the dorsal nerves with the exception of the first two, a series of fine nerves arise connecting these somatic nerves with the sympathetic system. These visceral, splanchnic, or white rami communicantes innervate through the sympathetic trunk the viscera and vessels of the splanchnic area. In making paravertebral injections the object is to bathe the nerves at their point of division and produce anæsthesia in the zone supplied by both the primary divisions and the sympathetic twig. After emerging from the intervertebral foramen each nerve lies between adjacent transverse processes and runs in the intercostal space towards the angle of the rib above; it is accompanied by an artery and vein. In this space extending from the tubercle of the rib to the costal angle the nerve lies between the external intercostal muscle and the internal intercostal membrane, which alone separates the nerve from the pleura and lung. Continuing its course in the intercostal space each nerve travels around the thorax, giving off a lateral cutaneous branch in the midaxillary line and an anterior cutaneous branch in front. The upper nerves supply the chest wall; the lower the integument of the abdomen and part of the back.

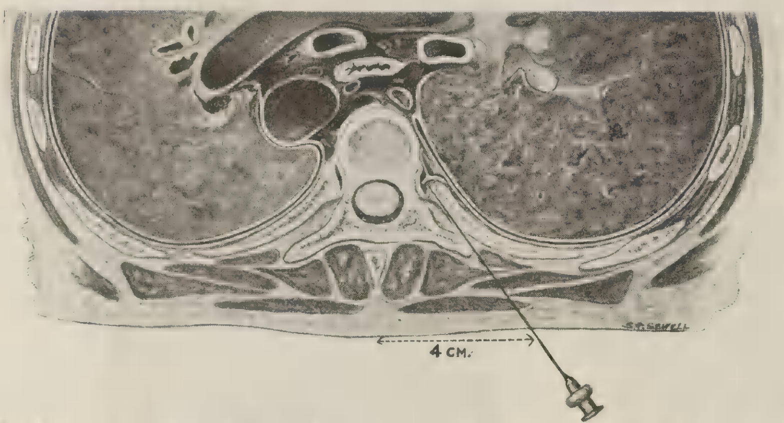
FIG. 2.



Transverse section of neck: level of fourth cervical vertebra, showing needle in position. T.P., transverse process; C.V., cervical nerve; C.A., carotid artery; J.V., jugular vein.

Technique.—With the patient lying on the opposite side, the back arched, and a pillow under the loin, the twelfth spinous process is identified in the following way: A perpendicular drawn from the last rib at a distance of 5 cm. from the mid-line passes through the transverse process of the twelfth dorsal vertebra; an alternative way is to count upwards from the fifth lumbar transverse process. At a distance of 4 cm. from the mid-line dermal wheals are raised opposite the transverse processes at the desired level. A needle 9 cm. long is inserted through the wheal and inclined outwards to an angle of 45° with the sagittal plane of the body. The needle is directed forwards and inwards and contact is made with upper and lower transverse processes in turn, the needle is then passed forwards and inwards between the two transverse processes and anterior to the lamina till it impinges on the side of the vertebral body immediately in front of the inter-vertebral foramen (Fig. 3). After preliminary aspiration 5 c.cm. of 1 per cent. novocaine is injected. If during the progress of the needle paræsthesia is established the injection is made at once. As many nerves as necessary are injected and the field tested with a sharp needle; if a band of normal sensation is found the particular area is injected again. Puncture of the pleura is painless, but injection in the pleural cavity gives rise to coughing, and, of course, no anæsthesia is established. Puncture and injection of the lung give rise to pain and coughing. The upper dorsal paravertebral block is indicated for operations on the chest, and in conjunction with the brachial plexus block for operations on the upper limb, the axilla, and for radical amputation of the breast. The lower paravertebral (seventh to twelfth) can be used for upper abdominal operations (Fig. 4), but, as will be explained later, it is not the method of choice.

FIG. 3.



Transverse section at level of fifth to sixth dorsal vertebra (Specimen No. 252B, Roy. Coll. Surg. Mus.), showing needle in position.

LUMBAR PARAVERTEBRAL.

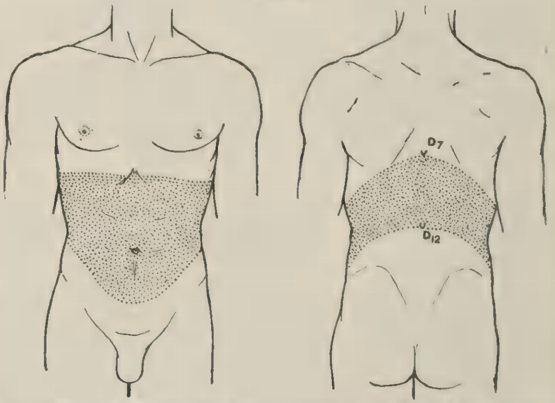
The lumbar plexus is situated in the substance of the psoas muscle; the four upper lumbar nerves which contribute to its formation, after emerging from the intervertebral foramina course slightly downwards and lie in close relationship with transverse processes; the first lumbar nerve in front of the second lumbar transverse process, and so on. The branches of the plexus are: The ileo-hypogastric and ileo-inguinal from the first, the genito-crural from the first and second, the external cutaneous from the second and third, the anterior crural and obturator from the second, third, and fourth; the remainder of the fourth with the fifth form the lumbo-sacral cord. The cutaneous area supplied by these nerves occupies the lower part of the abdomen and part of the back and the anterior and inner parts of the thigh. The guide to the nerves are the transverse and spinous processes of the lumbar vertebræ. It will be observed that the spinous processes are vertical laminæ about 2 cm. in height and that their upper border corresponds with the transverse processes which are short and directed outwards at right angles to the spinous processes.

Technique.—With the patient lying on the opposite side in the same position as for the induction of dorsal paravertebral, the spinous processes of the lumbar vertebræ are identified by counting from the first or from the fifth. Each spinous process is palpated till its upper border is felt, a wheal is raised at that level 3 cm. from the mid-line. A needle 10 cm. long is introduced through the wheal and directed antero-posteriorly till the transverse process is reached; the needle is then made to pass over the upper border of the transverse process. It is the rule to induce paræsthesia as the nerves are of large size; 8 c.cm. of novocaine is injected around each nerve. To anæsthetise the fifth lumbar nerve, the needle is inserted below the fifth transverse process. Lumbar paravertebral is used in combination with the lower dorsal for operations on the kidney and ureter; anæsthesia is complete and the most difficult renal operations have been done without a general anæsthetic (Fig. 5). It has the advantage of not throwing an additional burden on the opposite kidney.

SPLANCHNIC ANALGESIA.

The most interesting and perhaps the most important part of regional anæsthesia is splanchnic analgesia. It is not only a valuable addition to practical surgery but has opened up a field of research. It allows the surgeon to interfere to a more extensive degree in the upper abdomen and robs major abdominal operations of a great deal of their seriousness. The innervation of the abdominal viscera is derived partly from the vagus and partly from the sympathetic. Section of the spinal cord between the fifth and sixth dorsal vertebræ in a dog produces analgesia of the abdominal viscera (Kappis[4 5 13]). Section of the splanchnic nerves produces analgesia of the stomach, liver, gall-bladder, spleen, and small intestine. Section of the spinal nerves supplying the abdominal wall produces parietal anæsthesia only; visceral sensibility remains unaltered (Hoffman[13]). Application of novocaine gives similar results. The viscera, as is well known, are insensitive to cutting or cauterising, but the retroperitoneal tissue is very sensitive

FIG. 4.

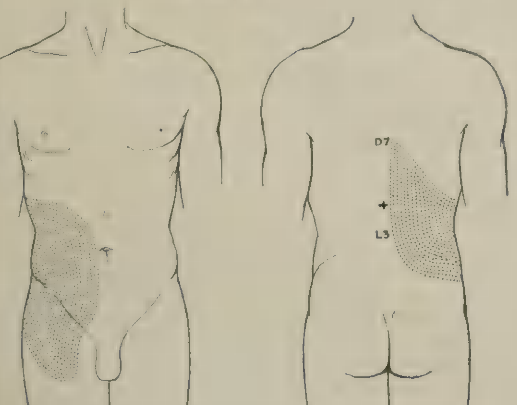


Area of anæsthesia after bilateral paravertebral block from seventh dorsal to twelfth dorsal nerves.

especially to pulling. Every surgeon is aware that the lesser sac of peritoneum and the region of the cœliac artery are exceedingly responsive to manipulations. The sympathetic fibres therefore collect and transmit to the cerebro-spinal system through the splanchnic nerves afferent impulses from the viscera. The solar plexus is a mass of considerable size composed of nerve-fibres intermingled with ganglionic cells; it is situated behind the peritoneum at the level of the first lumbar vertebra, in front of the crura of the diaphragm, near the origin of the cœliac axis. It is composed of three parts—the cœliac plexus proper and the two semilunar ganglia—situated close to the suprarenal bodies, the right being overlapped by the inferior vena cava. The plexus is continuous with subordinate plexuses—renal, phrenic, mesenteric, &c. Each semilunar ganglion is joined by the splanchnic nerves. The great splanchnic nerve is derived from the ganglionated thoracic sympathetic chain, and originally from the fifth to ninth dorsal nerves; the small splanchnic comes from the ninth and tenth dorsal nerves. They pierce the crura of the diaphragm and join the semilunar ganglia. Splanchnic analgesia is obtained by bathing with novocaine the retroperitoneal space containing the semilunar ganglia.

Technique.—The patient lies on the side opposite to that of the injection, a pillow under the loin. The site of the injection is found by identifying the twelfth rib and taking on it a point 7 cm. distant from the mid-plane of the body (Fig. 6). In cases where it is difficult to identify the last rib, the injection level is found by determining the spinous process of the first lumbar vertebra. A dermal wheal having been raised on the selected point, a needle 12 cm. long is introduced forwards and inwards at an angle of 35° for a distance of 8 or 9 cm. When the body of the first lumbar vertebra is felt, the needle is withdrawn and reintroduced at a smaller angle till it is felt to glide tangentially along the side of the vertebral body (Fig. 7). If the angle is less than 30° there is danger of transfixing the renal pedicle or the kidney; at an angle of more than 45° the intervertebral foramen may be entered. If no blood is withdrawn on aspiration 60–80 c.cm. of ½ per cent. novocaine is slowly injected. The solution diffuses in the retroperitoneal tissue from the diaphragm downwards along the bodies of the vertebræ. If the solution is coloured with indigo-carmine or methylene-blue, on opening the abdomen, it will be seen infiltrating a wide retroperitoneal area. The procedure is repeated on the opposite side; one dermal wheal and one puncture on each side is sufficient; ¾ g. of novocaine induces good splanchnic analgesia.

FIG. 5.



Area of anæsthesia after unilateral paravertebral injections from seventh dorsal to third lumbar nerves; suitable for operations on kidney and ureter.

FIELD BLOCK.

The anæsthetisation of the abdominal wall is obtained by injecting the sheath of the rectus muscle at a suitable level. Wheals are raised on each side of the outer border of the rectus at the level of the ninth costal cartilage and just below the umbilicus. A needle is introduced through each wheal till it is felt to puncture the anterior layer of the rectus sheath; this imparts a characteristic resistance to the needle and serves as a landmark; puncture of the sheath is painful. Half per cent. novocaine is injected into the muscle and deep to it in a fan-shaped manner radiating from the point of puncture; when the injection is carried out carefully the rectus muscle becomes relaxed and the parietal peritoneum insensitive to gentle manipulation. The subcutaneous tissue is next injected along the semilunar line through the same dermal wheals. It must be remembered when this procedure is adopted there remains a lateral zone of unaltered sensation. It is therefore important for the success of the field block that all incisions be made within the anæthetised area with a sharp scalpel and not scissors; retractors must be introduced gently and the edges of the wound separated gradually. If manual exploration is necessary the incision must be of adequate size, to admit the hand easily. The patient is aware that his viscera are being manipulated, but he does not complain of pain. In nervous patients, or for the mental comfort of the surgeon, a first-stage ether anæsthesia for a few minutes is a useful adjunct. The abdominal field block can be varied so as to suit various incisions.

FIG. 6.

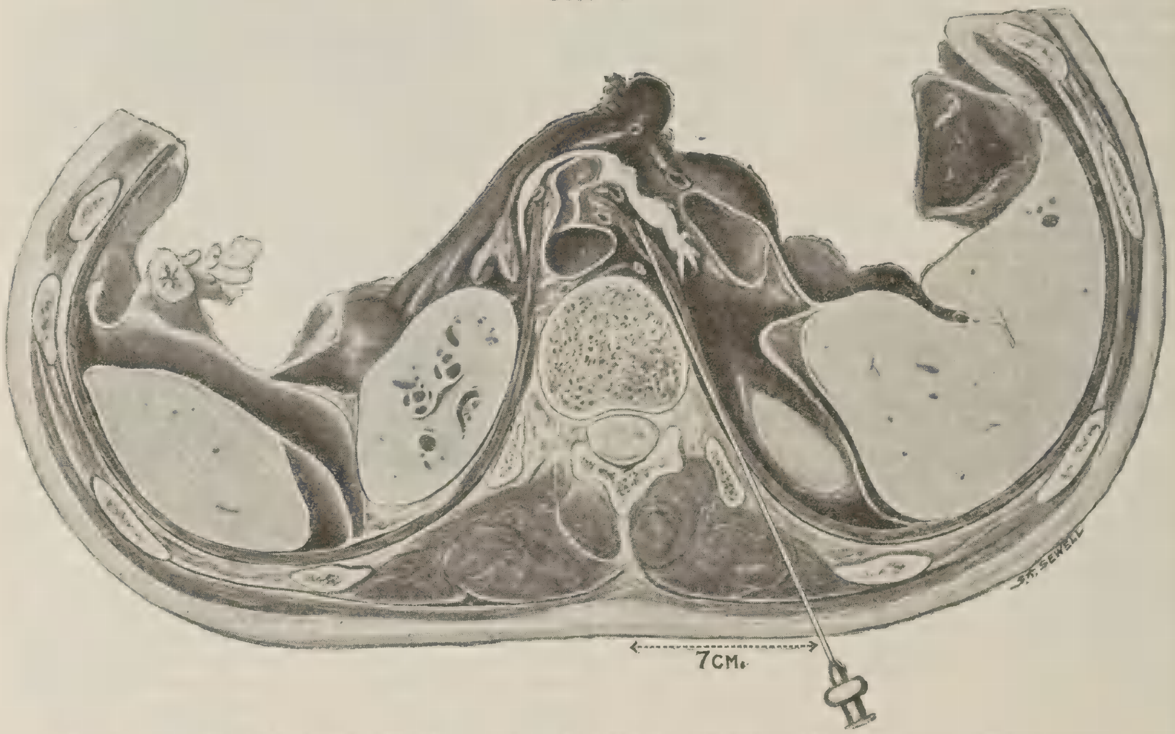
EXPERIMENTAL EVIDENCE OF REGIONAL ANÆSTHESIA.

To obtain some evidence of the effects of regional anæsthesia experiments were carried out on cats, rabbits, and dogs. The variations of blood pressure were taken as an index, not because it was considered that these were an accurate record of the various degrees of shock, but because it was the most convenient method of obtaining a graphic record. In all cases but two the animals were anæsthetised with ether, and the depth of anæsthesia in most cases was such that the conjunctival reflex was not lost. The blood pressure was recorded by connecting the central end of the carotid artery to a mercury manometer carrying a writing point. The experiments performed included abdominal section, manipulation of various viscera, twisting and dragging of the stomach and intestines.

gastrectomy, splenectomy, faradic stimulation of the peritoneum, viscera, splanchnic, and sciatic nerves. All the experiments were first performed under the influence of ether alone and then repeated after a local, regional, or splanchnic infiltration with ½ per cent. novocaine. Each addition of ether on the mask produced a slight fall of blood pressure. Manipulations of viscera produced a rise of blood pressure. To obtain a fall more violent manipulations had to be done. In rabbits a fall was more easily obtained. The viscera were kept moist and warm throughout the experiment, and inside the abdominal cavity most of the time. Exposure to air of a viscus rapidly produced loss of response to stimulation. The results were similar to those obtained by Prof. Pannett[17] in his experiments on anoci-association in 1914. Splanchnic anæsthesia was more effective than local applications. The experiments showed that, whilst under general anæsthesia, manipulations of the viscera produce alterations in the blood pressure, similar manipulations under regional anæsthesia had hardly any or no effect. Regional anæsthesia therefore blocks the paths of afferent impulses from the viscera and protects the medullary centres, in particular the vasomotor centre (Fig. 8).

Fig. 7.



Transverse section at level of first lumbar vertebra (No. 270C, Roy. Coll. Surg. Mus.), showing needle in position, perforating diaphragm posterior to right semilunar ganglion.

Further, histamine is a normal constituent of the intestinal contents and the toxæmia of intestinal obstruction is at least partly due to its absorption, and it has been shown that the etherisation of an animal makes it more sensitive to the effect of histamine. In practice it was found that splanchnic anæsthesia offered the patient a better chance of recovery from intestinal obstruction, besides the more obvious advantages of avoiding inhalation accidents. Finally it was observed that intravenous injection of novocaine invariably produces cessation of respiration and a marked fall of blood pressure, leading to the death of the animal (Fig. 9).

Record of Cases and Results Obtained.

My series consist of 84 cases operated upon under regional anæsthesia. Of these, 35 cases were operated upon by my corresponding senior colleague—Mr. Arthur Evans; 32 by myself and the remaining 17 cases by the other surgeons at Westminster Hospital. Table I. shows the number of each type of regional anæsthesia employed. The 12 cases of cervical paravertebral comprise: 4 cases of excision of malignant cervical glands—all three were wide dissections by Crile's method; 6 cases of hemithyroidectomy: 2 for exophthalmic goitre, 1 for adenoma, 3 for parenchymatous goitre, including one case with marked dyspnœa, due to pressure on a deviated trachea and complicated by a large retrosternal lobe; and 1 operation for fractured clavicle. The remaining case was that of an epithelioma of the aryepiglottidean fold, with secondary deposits in the cervical glands. The operation consisted in the removal of the glands, ligature of the external carotid, lateral transthyroid pharyngotomy, excision of the primary growth, reconstruction of the pharynx, laryngotomy, and suture. The operation lasted two and a half hours. The patient was 61 years old; he left the table with a pulse of 90. There was no shock. He died in the third week from a mediastinal abscess. Two out of the 12 cases (one exophthalmic goitre and the last case mentioned) had light general anæsthesia towards the end of the operation.

Table I.—84 Cases.

Dorsal and lumbar	11
Epidural and sacral	2
Splanchnic	41
Field block only	14
Sciatic, obturator, &c.	2
Median, ulnar, &c.	2

Of the 11 dorsal and lumbar paravertebral, 9 were renal operations: 3 nephrectomies, 3 pyelolithotomies, 2 nephrolithotomies, and 1 nephropexy and appendicectomy. One patient on whom a pyelolithotomy was performed by Mr. Evans had marked curvature of the spine, and the space between the costal margin and the iliac crest was very narrow; unusual pulling on the kidney was necessary before the pelvis could be exposed. No general anæsthetic was necessary, the patient being comfortable throughout the operation. One nephrectomy was done for a pyelonephritis diagnosed five years previously at a genito-urinary hospital; operation was advised, but the patient, a lady of 49 years, preferred Christian Science treatment. When I saw her five years later she had a large tumour in the loin, rigors, purulent urine, and a very low percentage of urea. The kidney was universally adherent and difficult to deliver. The patient had very light general anæsthesia towards the end of the operation. Recovery was uneventful.

The remaining two cases of dorsal paravertebral are of interest.

One was an enormously fat woman, 63 years of age, on whom I operated seven days previously for left posterior subphrenic abscess. She was extremely ill and cyanosed; in the upper part of the abdomen an indefinite tender swelling could be felt deep down behind the extremely adipose abdominal wall; the abscess was still draining. The temperature was 103° F., pulse 130, respiration 35. General anæsthesia was quite out of the question; under regional anæsthesia a transverse incision was made below the costal margin on the left side, through the rectus muscle. A large collection of pus, débris, and gastric contents were evacuated from the lesser sac of peritoneum. The patient recovered. (She died four months later from heart failure.) In one case the third to fifth lumbar and the first and second sacral were injected for persistent pain following a Fourneaux-Jordan amputation done three weeks previously. The relief of pain was rapid, complete, and permanent.

The epidural and sacral block was done in two cases, both for perineal excision of the rectum, performed by Mr. Evans. The 14 cases of field block are shown in Table II. Of these, 11 were successful and three were failures, owing probably to errors of technique. Table III. shows the cases operated upon under splanchnic analgesia. A far larger number of cases was actually done, but I have discarded from this table all those cases that needed a general anæsthetic, after the abdomen was opened.

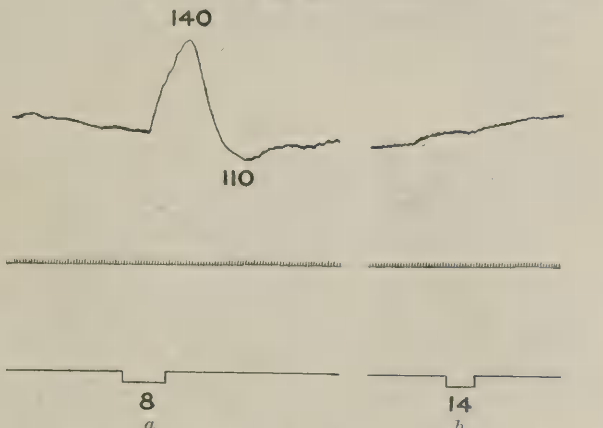
After inducing splanchnic anæsthesia there is generally a slight fall of blood pressure for 10 or 15 minutes, then the blood pressure rises above normal, the pulse becomes slower. Some patients complain of nausea when the stomach is manipulated; in the cases in this table the analgesia was successful, and the following important points were noticed: (1) Relaxation of the recti was perfect; (2) manipulations of the viscera, even when doing a gastrectomy, had little effect on the blood pressure; (3) there was complete abdominal silence; (4) suturing the abdomen presented no difficulty. In other cases, however, parietal anæsthesia alone was obtained. In these ether was administered. It is very important that only the light first stage should be aimed at, as if the second stage is reached the patient begins to struggle and a good deal of the benefit of the regional method is lost.

In cases of acute intestinal obstruction splanchnic analgesia has no rival. I will quote one case:

I was asked to see a woman aged 70; she had intestinal obstruction of four days' duration. I was shown several bowls of fæcaloid material vomited by the patient during the day. The abdomen was distended, constipation was absolute, the pulse weak and at the rate of 110, temperature was normal. The operation was done under splanchnic analgesia, a loop of small intestine strangulated by bands was resected and end-to-end anastomosis performed; a tube was inserted in the small intestine above. I am convinced the patient would not have survived the operation had a general anæsthetic been given.

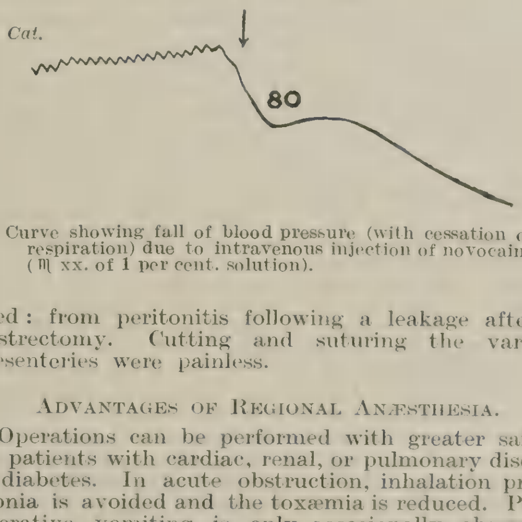
FIG. 8.



Blood-pressure tracing of a cat before (*a*) and after (*b*) splanchnic anæsthesia: effect of violent manipulation of stomach on blood pressure shown at 8 and 14.

Cholecystectomy was done in ten cases, hemicolectomy for carcinoma of the cæcum and ascending colon—twice; of the six gastrectomies, four were for chronic ulcers situated high up on the lesser curvature, one for a pyloric ulcer and one for carcinoma of the stomach. Of all these cases, only one died: from peritonitis following a leakage after a gastrectomy. Cutting and suturing the various mesenteries were painless.

FIG. 9.



Curve showing fall of blood pressure (with cessation of respiration) due to intravenous injection of novocaine (♏ xx. of 1 per cent. solution).

ADVANTAGES OF REGIONAL ANÆSTHESIA.

Operations can be performed with greater safety on patients with cardiac, renal, or pulmonary disease or diabetes. In acute obstruction, inhalation pneumonia is avoided and the toxæmia is reduced. Post-operative vomiting is only occasionally observed. There is marked diminution of shock. It is sufficient to witness a patient at the end of a severe operation to realise the value of the method. The charts show (Fig. 10) the condition of the blood pressure and the pulse-rate throughout a prolonged operation. What concerns pulmonary complications, it is claimed that those complications due directly to the inhalation of ether or chloroform are abolished. It is not claimed that the incidence of pulmonary embolism will in any way be affected by regional anæsthesia; but the effects of the vapour on the lungs is abolished. I quote from Prof. McDowall[19]: "It does not seem to be appreciated that the lung tissue may, apart from mere irritation, suffer serious damage as a result of actual contact with the vapour of ether or chloroform." Further, under deep ether or chloroform anæsthesia, "the bronchioles do not contract (Brodie and Dixon quoted by McDowall) and the alveoli are exposed to particles which otherwise do not reach them." This accounts for such post-operative pulmonary complications which are preventable by substituting regional for general anæsthesia. Of all the cases in my series, none developed pulmonary complications. As regards reduction of mortality, the figures are too small to carry any conviction, but of all the 84 cases considered here, only four cases died—a mortality of 4·7 per cent., which compares favourably with the general mortality of the surgical cases of the same hospital, especially if it be taken in consideration that in many cases much more extensive operations were performed than would have been the case under general anæsthesia.

Disadvantages of the Method.

To the patient, even under the influence of morphine and scopolamine, the multiplicity of the punctures necessary for the induction of anæsthesia is irksome; repeated contact of the needle with the periosteum or nerve trunks is very trying. Also, the psychic element must be taken in consideration. The public, as well as the profession, has yet to become accustomed to regional anæsthesia. I am at present engaged in finding suitable doses and methods of administration of drugs which induce sleep and raise the blood pressure. I have reason to believe that, with suitable administration of chloralose or a similar drug, regional anæsthesia will become popularised. At present it is essential, as the patient is conscious, that absolute silence be maintained in the theatre; the patient must not see or hear the instruments; he must not be asked if he is being hurt—he will soon volunteer the information if he is.

To the surgeon there is the disadvantage at present to have to induce the anæsthesia himself, or to obtain the services of two anæsthetists. The surgeon must also understand that his technique must be adapted to regional methods. He must be gentle with intent, right through the operation. He must discriminate between complaints due to pain and those due to nervousness.

Although the toxicity of novocaine is very low, its use is sometimes followed by signs of intolerance; these have occurred in two cases: there were pallor, tachycardia, cyanosis of the finger-tips, and sweating. An injection of pituitrin or caffein quickly restores the patient's condition.

In one case, after a unilateral paravertebral from the sixth to the twelfth dorsal nerves, there was marked pallor of one-half of the face on the side of the injection, in great contrast with the flushed appearance of the opposite side; also the pulse at the wrist on that side was imperceptible, whilst on the opposite side the pulse was normal in volume and frequency; the general condition of the patient was good. In two cases, one paravertebral and one splanchnic, the blood pressure dropped suddenly during the induction, and respiration ceased. It was due to the inadvertent injection of novocaine into a blood-vessel. Both patients recovered.

One case of inoperable carcinoma of the liver and gall-bladder suddenly became unconscious at the end of the operation, and died 24 hours later without recovering consciousness.

Conclusion.

Regional anæsthesia has been in existence 20 years. From my personal observations of the method as used by Prof. Pauchet in Paris, from the experience of my own cases, and from the study of experiments on animals I am led to the conclusion that regional anæsthesia has its place not only as a life-saving measure in the surgery of the old, the feeble, and the diseased, but as a routine measure in numerous routine surgical procedures.

The experimental work was performed in the physiological laboratories of King's College, and I am indebted to Prof. McDowall for the facilities afforded, and his criticism of the work. Finally, I wish to thank Mr. Evans for the interest he took in the method since I began to use it; for his willingness to operate under regional anæsthesia, and for his help and encouragement on numerous occasions. And I take this opportunity to express my appreciation. My thanks are also due to Mr. Rock Carling, who used the method on 14 occasions, and to Mr. C. Price Thomas, for his constant and ungrudging help in the operating theatre, the physiological laboratory, and for the preparation of the dissections used to illustrate this lecture; and to Mr. Sewell, I am indebted for the illustrations.

SPLANCHNIC ANALGESIA,

WITH RECORD OF NINETY-ONE CASES.*

I.—SURGICAL ASPECT.

BY O. STANLEY HILLMAN, M.S. LOND.,
F.R.C.S. ENG.,
SURGICAL REGISTRAR, MIDDLESEX HOSPITAL.

II.—ANÆSTHETIC ASPECT.

BY RAYMOND E. APPERLY, M.R.C.S.,
L.R.C.P. LOND.,
HON. ANÆSTHETIST TO THE ABOVE HOSPITAL.

I.—SURGICAL ASPECT. *By* MR. HILLMAN.

THE principles of anoci-association as brought forward by Crile are known to you all and no doubt practised by many. That this method gives great advantages to both patient and surgeon there is, I think, no doubt, but as the method consists of the production of a local or infiltration anæsthesia in the operative field it has its limitations and perhaps disadvantages. I propose to put before you a method which is based on Crile's principles but differs in that the analgesia produced is regional and not local, and for this reason enables the method to be applied to the blocking of impulses passing from the abdominal viscera to the central nervous system.

Splanchnic analgesia consists in placing a block across the path of impulses passing from the viscera via the cœliac ganglia and the great splanchnic nerves to the central nervous system. This is done by placing a certain amount of 1 per cent. novocaine in the path of the splanchnic nerves.

Basic Principles.

It is necessary to show that splanchnic analgesia is based on sound principles. To do this I cannot do better than refer to an article by Prof. C. A. Pannett in the *British Journal of Surgery*, Vol. II. Prof. Pannett shows by animal experiments that novocaine placed in relation to the mesenteries of the viscera definitely protects the animal from shock produced by handling those viscera. He also shows that the rigidity of the abdominal wall in operations on the abdomen is considerably reduced when the mesenteries of the viscera operated upon are infiltrated with novocaine. This shows that the rigidity of the abdominal wall is not entirely due to irritation of the parietal nerves, and therefore injection of these nerves alone will not give the same relaxation as if the visceral nerves are blocked as well.

I am fortunate in having a clinical example of this. I was asked to give a splanchnic anæsthetic to a patient with a perforated gastric ulcer who was very ill. When I saw him he was groaning and writhing with pain and his abdominal wall was board-like. With great difficulty I succeeded in performing the injection, and when I turned him on to his back I was surprised to find him lying quite peacefully and apparently without pain. I spoke to him and he volunteered that all his pain had vanished. This gave me remarkable proof of the efficacy of the splanchnic block.

The important fact to be grasped from this is that afferent impulses do pass to the central nervous system from the viscera, and that these impulses can be interrupted by placing a block across the visceral nerves. This is the justification for splanchnic analgesia.

In the human subject the upper abdominal viscera are supplied by nerves through the great splanchnic nerves, which are derived from the fifth to the ninth or tenth dorsal nerves and also by the lesser and least splanchnic nerves which run in close proximity. These nerves pass through the crura of the diaphragm and are distributed to the various viscera via the cœliac ganglia. For the induction of splanchnic analgesia it is necessary to place novocaine in the path of these nerves, and this is done at the level of the first lumbar vertebra.

In order to complete the analgesia for an abdominal operation it is of course necessary to place a block across the paths of the nerves of the abdominal wall. This is done by performing an abdominal field block, the technique of which I described fully in my article on Splanchnic Analgesia in THE LANCET, July 5th, 1924.

Technique.

It is of course possible to operate under splanchnic analgesia alone, and when I commenced this procedure this was done with considerable success. This method must mean a considerable amount of psychic shock to the patient, it certainly entails a great deal of mental strain on the surgeon to perform a major operation on a conscious subject, and it certainly is more of a strain to perform the injection on a person who may move at any moment. For these reasons I changed the technique and now give the injection under light ether anæsthesia which is continued throughout the operation, so that the splanchnic injection is used as a means of reducing shock and reducing the amount of anæsthetic drug administered, both of which objects have been fully attained.

In my article quoted above, I gave a full description of the technique of the splanchnic injection, and in THE LANCET of July 12th (p. 70) I gave a description of the syringe that I had made for the purpose. Since then I have slightly modified the procedure, for instead of making the injection opposite the first and second lumbar vertebræ I now make it opposite the first only. In this way, after striking the first lumbar vertebra and getting the needle in the correct position 1 cm. beyond, an injection is made of 30 c.cm. of 1 per cent. novocaine, the needle is then withdrawn, and the same injection made on the other side. It will be seen, then, that the dose of novocaine has been reduced from 90 c.cm. for the splanchnic injection to 60 c.cm., and equally good results seem to be obtained.

The technique is not difficult, but it must be carried out in detail and with great care, and especially must aspiration *always* be done before injecting the novocaine, for, should that quantity of novocaine be discharged into the blood-stream, the result would be a fatality. It is essential for good results that the operator have a mental picture of where his needle is going; if he has not he cannot overcome any difficulties that may arise, and also he may become careless and forget that his needle is in a dangerous area.

It need hardly be pointed out that gentleness is essential. This is especially the case when making the injection on a conscious subject, though unconsciousness must be no excuse for roughness. If the bone be struck roughly the point of the needle will be turned and will tear the tissues on withdrawal, unnecessary shock will be caused, and in a conscious patient pain.

Advantages and Disadvantages.

I will now proceed to discuss the following points: (1) The advantages and the disadvantages to the surgeon; (2) the advantages and the disadvantages to the patient; (3) the effects on the pulse-rate and the blood pressure.

1. *Advantages to the Surgeon.*—The most striking phenomenon on watching a case under splanchnic anæsthesia is the smallness of the respiratory excursion as compared with those of a similar case under purely ether anæsthesia of as light a depth; this is, of course, of immense help to the operator. There is complete and perfect relaxation of the abdominal wall with a light depth of anæsthesia. There is complete absence of sudden straining on the part of the patient when any necessary traction is made. This is

---

* Delivered before the Section of Anæsthetics of the Royal Society of Medicine.

especially seen when operating on the gall-bladder and ducts. It is well recognised how difficult some patients can be when operations are carried out on the biliary tracts, straining and deep respirations occurring on the least traction: all this is eliminated if the splanchnic nerves have been successfully blocked. Lastly the surgeon is relieved of any anxiety, as he knows that his patient is receiving no shock, though this again must be no excuse for rough operating. The surgeon also is left with a free hand to do whatever he may think best for his patient, even though it involves a great deal of time and manipulation.

2. *Disadvantages to the Surgeon.*—These are, perhaps, two in number, though I think that they are easily overcome by the benefits that the patients derive. The first is the addition of 15 minutes to the time to anæsthetise the patient. This is the time that I now take to perform the injection, though at first, of course, it took longer. The second is the fact that if the operation be a long one the effect of the field block of the abdominal wall may wear off, though I think that this is really an error in technique than a real disadvantage. If this occurs it can readily be overcome by the coöperation of the anæsthetist, who, after the experience of a few cases, will recognise if deepening of the anæsthesia be needed or not.

3. *Advantages to the Patient.*—I will merely state what we consider these to be, leaving Dr. Apperly to deal with them in more detail: (1) The patient receives less anæsthetic drug; (2) there is the minimum of shock; (3) there is no fatigue from excessive respiratory excursions; (4) there is no "falling off" of the condition of the patient after return to the ward, as is so often the case after ether anæsthesia; (5) the day following operation the patient is in better condition owing to the absence of shock; (6) owing to the diminution of the amount of the anæsthetic drug administered there is less vomiting; (7) there is less liability to chest complications; (8) there appears to be less post-operative pain; (9) some patients who would be considered beyond surgical aid can be given the chance of an operation by means of splanchnic analgesia.

4. *Disadvantages to the Patient.*—In a few cases there has appeared to be a tendency to flatulent distension of the abdomen, but its incidence does not seem to be greatly increased. In one case a patient complained of severe neuralgic pain in the back. It was, however, never definitely established that the pain was due to the injection, though perhaps it is better to regard it as such. Some cases have suffered with severe headaches of two or three days' duration.

Effects on the Pulse-Rate and the Blood Pressure.

In a number of cases operated upon by Mr. Gordon-Taylor under splanchnic analgesia I have taken readings of the pulse-rates and blood pressures and from these readings prepared graphs. Most of the cases from which these graphs were obtained were partial gastrectomy cases, though some were laparotomies for suspected ulcers in which little was found, and only the appendix removed; however, whatever the operation, all the graphs show the same sequence of events. There is a distinct fall of blood pressure after the injection is made, this fall lasting on the average for 20 minutes; after this time the pressure steadily rises throughout the operation, until in about an hour's time it has reached the patient's normal level or even in many cases surpassed it. The fact that there is the same fall whether it is a severe operation or not, and that the pressure is higher at the end than at the beginning of the operation shows that the fall cannot be attributed to shock.

With regard to the pulse-rates, these in all cases show little variation from the normal, a fairly even rate being maintained throughout the operation. The striking point is that when the pressure falls the pulse-rate does not rise, sufficient proof that shock is absent and also that the fall in blood pressure is not dangerous.

Commentary on Cases.

I have now performed the splanchnic block on 49 cases; of these 38 were upper abdominal ones, and of the 38, 26 were partial gastrectomy cases. Of this series not one patient has developed any chest complication and only two died immediately after the operation. These two patients were so desperately

(48) Died 3 days after; heart failure.

ill that it was only the fact that splanchnic analgesia could be used that enabled them to be given the faint chance of an operation. That is to say, that out of 49 cases there were no chest complications and no deaths from shock, although the series contains some very difficult upper abdominal cases and that at least one patient had a very definite bronchitis and one a tuberculous lesion of the lung on account of which he had been refused operation at another hospital.

A comparison of 31 cases of partial gastrectomy with and without splanchnic analgesia is interesting. This shows that the average pulse-rate after operation has dropped by 26 and the deaths from shock to have been reduced from 12·9 per cent. to 3·2 per cent. (the one death being one of the desperate cases mentioned). Table I. shows that the number of blood transfusions has fallen from 14 to 2, and in both the latter it was given for previous hæmatemesis and not for shock.

I trust that I have shown that splanchnic analgesia has a definite value in abdominal surgery. I do not think that all upper abdominal cases need it, though I think that they are all the better for it. In the case of gastric surgery, however, where the extent of the lesion is always doubtful until the abdomen is opened, I do suggest that the surgeon will be happier in what he does if he knows that the splanchnic nerves are blocked. Therefore for these cases I suggest that splanchnic analgesia should be induced as a routine, and be combined with as little general anæsthetic as possible. In this way shock will be overcome and the chance of the patient developing a chest complication will be reduced to a minimum.

Hæmorrhage from suture line.

In conclusion, I wish to express my gratitude to Mr. Gordon-Taylor for his encouragement, and especially his patience, during my early trials, and also for his permission to base this paper on the cases that he has operated upon. I would also like to acknowledge the keenness with which the honorary anæsthetists of the Middlesex Hospital coöperated with me in this work.

II.—ANÆSTHETIC ASPECT. *By* DR. APPERLY.

One cannot help feeling that some anæsthetists have in the past rather looked askance at, if not almost resented, the introduction of any method of regional or local anæsthesia. One reason for this may be the dislike common to most of us, particularly as we get older and perhaps busier, of making the effort involved in mastering a new technique and shouldering a new anxiety. However that may be, the fact remains that few anæsthetists in this country use regional methods, and many still even leave spinal anæsthesia to be done by the surgeon if the case requires it.

Had it not been for the constant help and encouragement of Mr. Gordon-Taylor and Mr. Hillman, and my other surgical colleagues at the Middlesex Hospital, I should not have had the courage to attempt splanchnic block and other methods of regional anæsthesia. Since we first tried it, Mr. Hillman or myself have done a splanchnic block with abdominal field block in every gastric case which has passed through our hands in which a partial gastrectomy was anticipated, and also, as our lists show, in other operations in the upper abdomen which we thought presented special surgical difficulties, or where the patient suffered from chest complications.

I personally have no longer any doubt that combined regional and general anæsthesia will in the future be very largely used in all the more extensive surgical procedures. It is already used in abdominal-perineal excision of the rectum, Wertheim's hysterectomy, and often in prostatectomy; and recently we have used it with success in block dissections of the neck. I consider that the anæsthetist is the most desirable person to give the regional, as well as the general, anæsthetic. In a big case the surgeon has quite enough to worry him without having to attend to part of the anæsthetic arrangements, and few patients in private practice would like to pay the fees of both a regional and general anæsthetist. I would therefore urge anæsthetists to take a greater interest in regional methods as an addition to, rather than a substitute for, their present armamentarium.

Perhaps the greatest drawback to regional anæsthesia is the time taken in doing it. This particularly applies to hospital work, where a busy surgeon, with much to do and little time to do it in, may unconsciously discourage the anæsthetist from undertaking any new work because of the extra time involved. I am, however, sure that in some cases the results obtained by combined regional and general anæsthesia are so strikingly good as to justify the extra time taken, and besides, as the anæsthetist becomes more experienced in the method, the time taken is very greatly shortened.

Technique.

Splanchnic anæsthesia presents no great difficulties from the anæsthetist's point of view, provided the method has been practised sufficiently in the post-mortem room, and the technique which Mr. Hillman has described is carried out in every detail. In the first few cases no general anæsthetic was used except towards the end of the operation, by which time the abdominal field block was wearing off, and a little general anæsthetic was given for stitching up the abdominal wall.

In these cases morphine gr. ¼, scopolamine 1/100, was given one and a half hours before operation and morphine gr. ⅙, scopolamine 1/200 half an hour before. We quickly found, however, that a light general anæsthesia throughout did no harm, but had the following distinct advantages. (1) There was no need for the large preliminary dose of morphine and scopolamine which was almost a necessity if no general anæsthetic was given. (2) The splanchnic block was made much easier, took less time, and was, of course, painless. (3) Towards the end of a large operation, when the field block is wearing off, the anæsthesia can be quickly deepened and the closure of the abdominal wound facilitated. (4) Psychic shock was abolished. (5) The strain on the surgeon, to say nothing of the anæsthetist, is lessened if they are dealing with an unconscious patient.

Therefore after the first few cases the anæsthetic technique has been as follows: Morphine gr. ⅙ or ¼, atropine gr. 1/100, was given three-quarters of an hour before operation. General anæsthesia was induced, either gas and ether or chloroform and ether, and the splanchnic and abdominal field block then done in the anæsthetic room. Directly that is done, generally occupying about 20 minutes to half an hour, the patient is taken into the theatre, and general anæsthesia maintained with ether and oxygen, or chloroform and ether and oxygen. The abdominal incision should not be made until five minutes after the abdominal field block is finished.

Effect on Blood Pressure.

The blood pressure commences to fall shortly after the first splanchnic injection and reaches its minimum at the end of about half an hour, from which time it commences to rise again until by the end of one hour it is, as a rule, actually back to what it was before operation. In other words, the fall in blood pressure is of very short duration. It may be well to mention that it is extremely important to move the patient gently after the injections are made, and to avoid raising the shoulders too high, otherwise the blood pressure may fall very rapidly.

In private practice, of course, the anæsthetist, after inducing anæsthesia, has to call to his aid the doctor of the case or the surgeon's assistant to maintain a light anæsthesia while the regional blocks are done. It is extraordinary how light an anæsthesia can be maintained after the first injection. Patients who have been difficult during induction become quite placid, presumably owing to the fall of blood pressure. I would emphasise the point that the regional blocks cannot be hurried, but to be successful must be slowly and deliberately done. The anæsthetist will be aware of the success or otherwise of the splanchnic anæsthesia directly the surgeon handles abdominal contents. If the splanchnic block is effective the breathing should neither alter in rhythm or rate, even when considerable traction is put on any of the contents of the upper abdomen and the general anæsthesia is light.

With splanchnic anæsthesia, as in all other forms of regional or local anæsthesia, even when accompanied by light general anæsthesia, if the best results are to be obtained, there must be coöperation between the anæsthetist and surgeon. The anæsthetist must ascertain the exact position of the incision the surgeon proposes to make before doing his field block and even make his area of anæsthesia sufficiently wide to allow of a slight extension of the wound if necessary. On the other hand, the surgeon must not stray outside the anæsthetic area without warning the anæsthetist first, so that the nerve block may be extended or the anæsthesia deepened. In the same way heavy retractors used too forcibly or muscle torn instead of cut may pull on tissues outside the blocked area, and render a deepening of the general anæsthesia necessary, and then part of the benefit of the nerve block may be lost. One of the great advantages of the method is the quiet respiration and absence of movement of the abdominal contents; but once this is disturbed it is often difficult to restore it again. Thus the sudden thrusting of a hand without warning into the pelvis—an unanæsthetised area—in the course of an operation on the upper abdomen may create difficulties for both surgeon and anæsthetist.

It cannot be too strongly urged on the surgeon who wishes to get the best results from regional anæsthesia that gentleness in the treatment of the tissues is absolutely essential. In dealing with the advantages and disadvantages as we think of the method, I should like to take the disadvantages first.

Disadvantages of the Method.

1. *Fall of Blood Pressure.*—The blood pressure tracings demonstrate that the blood pressure falls often very considerably and very rapidly, but in only one case has it caused any anxiety whatever. It was in a case of cholecystectomy, where the patient's shoulders were lifted very suddenly in order that an air-cushion should be placed under the back. The anxiety, however, was very short-lived, as was the fall in blood pressure. However, this case taught us to exercise care in moving patients after the splanchnic injection has been made. Bearing this disadvantage in mind, we think that in cases where the patient has a very low blood pressure or where the circulation has been recently depleted by a gastric or duodenal hæmorrhage, it is wise perhaps to reduce the amount of novocaine used. One can reduce the amount used in the splanchnic block, say, to 20 c.cm. in each side, and that in the abdominal field block by using ½ per cent. instead of the usual 1 per cent. solution.

2. The second disadvantage we have found is *post-operative headache and backache.* Six or seven of our cases have suffered more or less severely from headache and backache. We have been rather at a loss to explain this, as although our technique has been practically the same throughout all the series, we have not had this complication arise in the last 40 odd cases. It is true we have become more dexterous with the needle and therefore have not damaged tissues to the same extent, but we cannot think that has been the real cause.

We thought that the fall in blood pressure might account for it; but in those cases in which the fall of blood pressure has been most marked there has been no headache. We think therefore that probably the real explanation of the disappearance of this disagreeable complication may be in the fact that we have latterly used a smaller amount of novocaine in our splanchnic block. One other possible explanation of the headache has occurred to me in that it resembles closely the headache which occurs after spinal puncture. In our earlier cases, on a few occasions, we tapped the spinal theca or a prolongation along the nerve, and cerebro-spinal fluid escaped, and this error in technique might furnish an explanation, especially as this complication has not arisen as we become more expert.

3. *Time Taken in Doing the Nerve Block.*—As I pointed out before, this is an undoubted disadvantage, especially in hospital practice. But if the mortality in severe operations in the upper abdomen is lowered by the use of splanchnic anæsthesia, as we think it is, no one will grudge the extra half an hour spent in the anæsthetic room.

4. One other slight complication has arisen in two of our cases which in fairness must be recorded. They were bad gastric cases where the stomach was not entirely empty. The cardiac sphincter being relaxed by the splanchnic block, when the stomach was handled by the surgeon gastric contents commenced to regurgitate. The passing of a stomach-tube was, however, difficult, as the patient was under very light general anæsthesia, and its introduction was at once resented. In neither case, however, did any harm result.

Advantages of the Method.

1. *Absence of Post-operative Pulmonary Complications.*—In our combined cases—numbering 91—we have only had one case in which there has been any post-operative lung complication. We think this is distinctly good in so large a series of upper abdominal operations. It, however, becomes strikingly good, if we take into consideration the fact that a number of the gall-bladder cases and some of those in which gastro-jejunostomy was performed were done by this method at the request of our surgical colleagues, owing to the existence of bronchitis or some other pulmonary complication. In none of these cases was the chest condition appreciably aggravated by their operation.

The one pulmonary complication which occurred was in the forty-first of my cases. The patient was a man of 59 on whom a partial gastrectomy was performed for a large gastric ulcer high up in the lesser curvature. It was a very difficult case and the patient was in the theatre 1 hour and 35 minutes. He developed broncho-pneumonia on the second and died on the fourth day. He had extensive broncho-pneumonia of both lower lobes. He was medically a very fit and suitable subject for operation, which makes his case the more disappointing. On the whole, therefore, we think that perhaps the most striking advantage of the splanchnic and abdominal field block from the anæsthetist's point of view is the absence of pulmonary complications in a class of case which has in the past been particularly prone to them.

2. *Quiet respiration* and diminished abdominal movement with which it is associated. This, as Mr. Hillman has pointed out, is a great help to the surgeon. It is, however, equally important from the anæsthetist's point of view, as quiet respiration does not exhaust the patient, a very important point if the operation be a lengthy one and the patient past middle life. In elderly patients with emphysema and bronchitis I am sure it is a most potent factor in preventing post-operative lung complications.

3. *Perfect relaxation* for which, of course, one relies entirely on the nerve blocks, until perhaps the closing of the abdominal wall in a long case.

4. *Small Amount of General Anæsthetic Used.*—I count this as an advantage, not from the point of view of the anæsthetist's pocket, but from the fact that the patient is very little upset after operation, and sickness is very greatly reduced.

In trying to give this unbiased account of our work we do not pretend that the method should be adopted in every operation on the upper abdomen, but we do suggest that it has been the means of saving the lives of some of the patients on our lists and enabled operations to be performed on others which would not have been attempted under general anæsthesia alone.

In conclusion, I have to acknowledge my indebtedness to Mr. Gordon-Taylor, Mr. Webb, and my other colleagues at the Middlesex Hospital for their patience, encouragement, and help.

YORKSHIRE'S CRIPPLED CHILDREN.—It is estimated that there are in Yorkshire 5000 children of school age needing orthopædic treatment, but the existing hospitals in the county can receive only 250. The position will shortly be eased by the provision of a new orthopædic hospital at Kirbymoorside, where there is an ex-Servicemen's Red Cross hospital, consisting of army huts and a stone bungalow. These buildings, which are in sound condition, have been presented by Mrs. Edward Shaw, of Welburn Manor, and the Right Hon. J. R. Ferens, of Hull, has given £5000. The new hospital has room for 100 beds and there is sufficient land to allow of considerable expansion. The income will be derived mainly from payments by local authorities in respect of patients sent by them.

APLASTIC ANÆMIA FOLLOWING TREATMENT WITH X RAYS.

BY JOAN M. ROSS, M.B., B.S.LOND.,
ASSISTANT PATHOLOGIST, ST. MARY'S HOSPITAL, LONDON.

FROM time to time cases have been described amongst workers with X rays and with radium, where the prolonged exposure to the rays has produced very severe blood changes with a fatal result. One of the earliest cases was that of an Italian worker, who had for 14 years been accustomed to work with a very hard focus tube, and who took little precaution for his protection.[1]

Mottram (1920), in a paper[2] dealing with the leucocytic blood content of individuals working with radium, describes a diminution in the number of red cells with a high colour-index. In his later paper[3] he reports three cases of profound anæmia with a fatal termination after an illness of a few months. Larkin (1921) reports[4] a case of acute aplastic anæmia in a man of 43, who had been working at radiography for 15 to 18 years. Faber (1923) not only quotes the above cases, but gives[5] a description of another case, and points out the similarity of the blood changes in the series. No post-mortem examinations were done in any of these except in the Italian case.

		R.B.C.	C.I.	W.B.C.	P. (%)	L. (%)
Mottram's cases.	(1)	1,100,000	0·68	1000	50	50
	(2)	800,000	1·3	1520	48	52
	(3)	527,500	0·84	850	13·5	40·5
Larkin's case		1,000,000	0·9	840	41	58

R.B.C., red blood corpuscles. C.I., colour-index. W.B.C., white blood corpuscles. P., polymorphs. L., lymphocytes.

L*, mostly lymphocytes in film.

In the first and fourth cases in the above series the colour-index at some time in the course of the disease had been 1 or over. The above cases presumably possessed normal hæmatopoietic organs at the outset.

The therapeutic action of radiation in blood diseases is of extreme interest. Both X ray and radium have now been given an extensive trial in treatment of the leukæmias, and it is generally held that life is prolonged by the use of one or other of these forms of radiation. Gilbert,[6] as long ago as 1914, published a thesis on the treatment of splenomedullary leukæmia by radium. He stated that the cure was not stable, that signs of leukæmia returned after some weeks had passed, and that with radium treatment after this relapse the number of the leucocytes diminishes less rapidly and the curative action is less effective than when used at first. Peabody,[7] three years later, reports on 36 cases treated, stating that there was general clinical improvement, rapid decrease in the size of the spleen, and that the leucocytes were reduced. Brant[8] states that the Rontgen ray does not cure leukæmia, but that it improves the general condition, restores the earning capacity, and has a favourable action on the erythrocytes. Schreiner and Mattick[9] regard deep Rontgen ray and radium as essentially the same, which view was also expressed by Gulland,[10] who endorsed the views of other workers, stating "all cases relapse after a longer or shorter time. . . . In the long run all cases die of the disease or of an intercurrent affection, but I feel sure that the average length of life is greater than it was before radiation became general, or than it is with any other form of treatment." Gulland further emphasises the need of frequent blood examinations during treatment. He stated that it is quite easy to carry radiation too far, and to produce a condition closely resembling pernicious anæmia with a high colour-index, numerous megaloblasts, and a low red count. This he regards as due to interference with the normoblastic function of the marrow, and remarked that radiation, if persisted in, would perhaps in the end lead to an aplastic anæmia. He added that he had never seen it progress so far. He stops treatment by radiation with a leucocyte count of 20,000, since the effect goes on for some time after radiation has been stopped.

A case is reported by Whitcher[11] in which radium treatment did produce an aplastic anæmia. A summary of his case is of interest, since it shows a close analogy with the case of aplastic anæmia following X ray reported later in this paper.

Clinical Records.

CASE 1.—A boy, aged 14, first took ill in July, 1919, Splenomedullary leukæmia was not diagnosed until April. 1920, when the liver and spleen were both enlarged, the spleen reaching to within 25 cm. of the symphysis pubis. The blood count was typical: R.B.C., 3,150,000 per c.mm.; Hb, 50 per cent.; W.B.C., 164,800, with excess of myelocytes, &c., in the film.

Radium treatment was given at monthly intervals until June, 1921, when the white count was 11,000 per c.mm. The patient was not under observation for the next two months. On Sept. 1st, 1921, the white count was 69,900 per c.mm., with a greater percentage of myelocytes than lymphocytes in the films. Radiation treatment was given that day and the count fell to 20,000 per c.mm. on Sept. 8th. Another treatment was given, and on the 29th it was found that the number of leucocytes had risen to 58,000 per c.mm. with a percentage of 58 lymphocytes in the films. The boy was readmitted to hospital with severe dyspnœa and weakness with irregular fever.

On Oct. 18th the blood count was: R.B.C., 1,148,000 per cmm.; Hb, 23·5 per cent.; C.I., 1·06; W.B.C., 310. A blood transfusion was given but with little benefit. On Nov. 1st his blood count was: R.B.C., 1,252,000 per c.mm.; Hb, 24 per cent.; C.I., 1; W.B.C., 380 (polymorphs, 18 per cent.; lymphocytes, 70 per cent.; basophiles, 12 per cent.).

This last count, taken just before death, is similar to those cases of aplastic anæmia among X ray and radium workers just quoted. The case is, moreover, very similar to the following:—

CASE 2.—A boy, aged 11 years, was admitted to Paddington Green Children's Hospital on April 11th, 1924. A history of influenza eight weeks previously, with subsequent loss of weight and pallor, was given. The immediate cause of admission was an attack of painful priapism; he had also complained of vague pains in the head and abdomen. On admission the boy was thin and pale. There was slight glandular enlargement. The spleen was enlarged to below the crest of the ilium. A blood examination was made resulting as follows: R.B.C., 1,870,000; Hb, 36 per cent.; C.I., 1; W.B.C., 643,000. The films showed a few normoblasts. The majority of the white cells were of the bone-marrow type, and a diagnosis of splenomedullary leukæmia was made. During the next fortnight the priapism persisted. There was irregular fever, the evening temperature averaging 100° F., the morning 98·6°. Benzol ♏5 in capsule was given daily. The spleen diminished slightly in size. Dr. Pierce Williams showed the case at the Royal Society of Medicine, and I am indebted to him for the notes up to this point.

On April 30th the patient was transferred to St. Mary's Hospital. On admission the spleen was palpable 3 inches below and 1 inch to the right of the umbilicus. The inguinal glands were hard but not enlarged, the axillary glands were not palpable. The superficial veins were easily seen. The first of the series of blood counts done in this department gave figures: R.B.C., 1,656,000; Hb, 24 per cent.; C.I., 0·72; W.B.C., 1,016,000 (see Table II.). Normoblasts were present in the film.

During his stay in the hospital until August 8th, X ray treatments were given on the dates as in Table I. The fall in the number of white corpuscles is also shown. The second table shows the changes in the percentage and total number of the white cells in the differential count. On August 8th the patient was sent to a convalescent home for six weeks. On his return he attended the out-patient department. On Oct. 1st his general condition was much improved. The spleen was much decreased in size and his blood count showed: R.B.C., 4,592,000; Hb, 64 per cent.; W.B.C., 82,000.

TABLE I. (Case 2).

Nov. 13th	3 mm. AL 4/5	12,000
,, 24th	—	1,300
Dec. 15th	—	900

X ray treatments were continued. After that of Oct. 7th the patient complained of headache and vomited his food. After the next, headache and vomiting lasted four days. The vomiting later became persistent and the boy was readmitted on Dec. 11th. He was very wasted and pale. The skin over the abdomen was pigmented. There was some rigidity of the abdominal muscles. The liver was palpable about 2 inches below the costal margin, and the spleen was hard on palpation and reached a point half an inch above the inter-tubercular line. He was dyspnœic and very weak. On the 13th his temperature rose to 103° F. and remained high. The blood count done on the 15th gave the very low figures: R.B.C., 622,000; Hb, 12 per cent.; W.B.C., 900. He was given a blood transfusion, which improved his condition temporarily, but the next day his temperature rose again to 102° and remained high until he died on the 22nd.

Post-mortem Examination.—The body was very much wasted; there was extreme pallor of all the mucous membranes; the skin over the abdomen was pigmented—deeply on the right side; there were a few petechiæ over the shins and round the ankles. Heart showed numerous subpericardial hæmorrhages; pericardium contained 2 oz.

of clear straw-coloured fluid; right auricle was much dilated; right ventricle slightly dilated; chambers contained a little tenacious clot; valves normal; myocardium showed very pronounced "tigering" in both ventricles, most in left. Microscopically there was patchy fatty degeneration of the muscle fibres, mostly under the endocardium; numerous small extravasations of blood under pericardium and in substance of myocardium; there were patches where the muscle-fibres, with poorly staining nuclei, stained deeply and uniformly with eosin, possibly areas of coagulation necrosis due to capillary thrombosis, such as is described in the bone marrow; aorta and blood-vessels normal; internal jugular and larger veins distended with blood. Lungs, pale, some œdema; a few small areas of hæmorrhage scattered through substance of lung; numerous sub-pleural hæmorrhagic spots. Microscopically, some areas showed hyaline thrombi in the blood-vessels, with areas of extravasation of blood into the alveoli, some recent, some presumably older, with hyaline change. Stomach showed some submucous hæmorrhages. Liver slightly enlarged; surface mottled; cut surface pale; sections showed central cells of lobules to contain much fat; there was no leucocytic infiltration; no free iron. Spleen weighed 275 gm.; firm; capsule thickened and opaque; cut surface increased fibrous tissue; no Malpighian corpuscles visible; pulp dark in colour. Microscopically, increase of fibrous tissue mainly round the small vessels with deposit of brown pigment containing free iron; blood spaces dilated; large phagocytic cells scattered in the sinuses, some loaded with iron-containing pigment. The pulp contained few cells, amongst which were only a few scattered myelocytes. Tonsils, enlarged; pus in crypts. Microscopically numerous areas having typical histological structure of bone marrow. Lymph glands, slight general enlargement. Microscopically normal, but containing a few scattered myelocytes; no areas comparable to marrow tissue found in tonsils. Bone marrow: that of ribs red in colour; that of femur a uniform pinkish colour throughout: tough and gelatinous in consistency. Microscopically showed profound changes; fine fibrosis throughout; only a few minute scattered islands of bone marrow cells; the scanty cells present in other parts are elongated cells, some containing free iron; in some areas thrombosis of the capillaries.

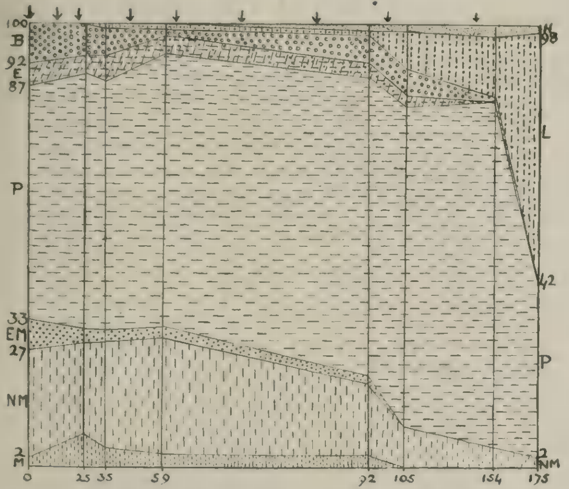

Diagram to show variations in differential count. Horizontal line represents time, numbers indicating days after beginning treatment. Vertical lines, numbers of various cells present in 100 cells. Arrows indicate dates of X ray treatments. M = myeloblasts and promyelocytes. NM = neutrophile myelocytes. EM = eosinophile myelocytes. P = polymorphonuclears. E = eosinophile polymorphs. B = basophile polymorphs. L = lymphocytes. H = hyalines.

This patient was originally admitted to St. Mary's Hospital under Sir William Willcox, and was later under the care of Dr. Reginald Miller, to both of whom I am indebted for permission to record the case.

Summary.

The blood examinations made during the earlier stages of this case leave no doubt that the boy was a typical case of splenomedullary leukæmia. At one time the improvement of his general condition was considerable (Oct. 1st, 1924). Later the blood picture changed rapidly. On Oct. 13th, unfortunately, no red blood count was done, but the white count was normal (9000) and the numbers of abnormal cells had fallen considerably. No counts after that of July 1st, 1924, showed any nucleated red corpuscles, which had been noted on previous occasions. The blood picture on Dec. 15th, 1924, was that of a severe aplastic anæmia, confirmed at autopsy.

The post-mortem findings in this case are remarkably like those reported by Whitcher. He, however, describes the bone marrow as being dark red, and microscopically containing numerous non-granular mononuclear cells. No fibrosis is described. Whitcher also describes some areas in the liver where the intercellular channels were distended into spaces which he presumes formerly contained myelocytes.

Spontaneous termination in anæmia of an aplastic type has not been described as taking place in cases of splenomedullary leukæmia. Both these cases seem to show that radiation either with X ray or radium may convert a case into aplastic anæmia. As is generally held, improvement takes place with the treatment, but it is only temporary and a relapse is to be expected. Exact details of the mode of termination of such cases after relapse are not often given. Whitcher's case shows a rapidly progressive aplastic anæmia. The two cases reported by Broadbent,[12] where the temporary improvement was followed by a further rise of the white cells and rapid termination, were regarded as a terminal acute lymphatic leukæmia. It seems probable that, as Letheby Tidy [13] pointed out, the abnormal cells were myeloblasts and that the termination was the recognised "myeloblastic" one. Such cases could be explained by supposing that the bone marrow was not so damaged as in the case now recorded, and could still respond to the unknown stimulus which produces the blood changes of splenomedullary leukæmia. On cessation of radiation the bone marrow did so respond.

It is obvious that more work needs to be done before the optimum dosage of radiation is fully known, before it is determined at what point the treatment should be suspended. The total number of white cells alone does not seem to be sufficient indication of the progress of treatment. The proportion of abnormal cells and any fall in the red count should be carefully taken into consideration.

JEJUNOSTOMY IN ACUTE GENERAL PERITONITIS.

BY SETON PRINGLE, F.R.C.S. IREL.,
SURGEON TO THE ROYAL CITY OF DUBLIN HOSPITAL.

Two years ago I published a paper in THE LANCET on The Cause of Death in Intestinal Obstruction.[1] That communication was an attempt on my part to give a résumé and analysis of the great amount of work which had been done on the subject. In endeavouring to draw conclusions I stated that the weight of both experimental and clinical evidence pointed strongly to intestinal toxæmia as being the chief factor in causing death; that this toxin was developed in the duodenum and to a lesser extent in the rest of the small intestine; and that, although it was not absorbed in the normal intestine, it was absorbed under the conditions which prevail in obstruction. In the same paper I also stated that I believed that death in acute septic peritonitis was not in most cases due to absorption of the products of the suppurative inflammation of the peritoneum but to intestinal toxæmia, secondary to paresis of the inflamed intestine, and, that if we could control this toxæmia there was a possibility of prolonging the patient's life for a sufficient time to allow the wonderful fighting properties of the peritoneum to deal with the infection. With this object in view I advocated the performance of a jejunostomy, by which means I believed that several apparently hopeless cases had been saved. Within the last two years I have employed this method in eight additional cases of peritonitis and I am fully satisfied that by its use some lives have been saved, and that in other cases convalescence has been rendered almost uneventful, although the conditions found at the operation were such as to lead one to expect a very anxious time.

Selection of Suitable Cases.

The class of case in which I would urge its use is the diffuse general suppurative peritonitis of the lower abdomen associated with appendicitis, tubal disease, and other septic conditions in the pelvis—the cases in which the intestines in the pelvis are acutely inflamed and the infection is already spreading upwards into the abdomen proper, so that, immediately on opening the abdomen, pus is seen lying between the congested coils of small intestine without limiting adhesions and, if a hand is passed down into the pelvis, a regular well of pus is found in the pouch of Douglas. In early cases the coils of intestine in the pelvis are at first dilated, but as the intensity of the inflammation increases they become collapsed and completely paralysed, while the coils higher up, where the inflammation is less acute, are dilated and paretic. When well established the condition is that so well described by Sampson Handley[2] as "ileus duplex"—a paralysis of the segment of pelvic colon and of the coils of small intestine which lie in the pelvis, with consequent dilatation of the proximal colon and upper ileum and jejunum. To deal with such a condition Sampson Handley advocates the performance of an ileo-colostomy to drain the upper small intestine, and a cæcostomy to drain the colon, but he naturally hesitates to adopt such an extensive procedure until satisfied that without it the patient's prospects of recovery are negligible. In other words, at the primary operation he merely deals with the cause of the infection and provides drainage of the peritoneal cavity, and then, if the peritonitis advances, he operates again a few days later and carries out the double drainage operation. I would like to advocate the performance of a jejunostomy in the first instance and I believe that then the necessity for the more extensive procedure would not arise—the jejunostomy will drain the upper intestine and the paresis of the pelvic colon can usually be controlled by enemata and pituitrin. I think Victor Bonney[3] was the first to recommend jejunostomy for these cases, but Sampson Handley, in a recent paper,[4] condemns its use, stating not only that it entails the loss by the patient of great quantities of fluid, but that a second operation for its closure is necessary should the patient survive. These objectionable results would certainly follow simple jejunostomy by the old methods of suture of the intestine to the parietal peritoneum, but both are obviated entirely if the operation is carried out as described in my previous paper as follows:—

> "The operation I have performed is after the manner of a Witzel's gastrostomy—a No. 12 soft rubber catheter is inserted into the lumen of the intestine through a small puncture and fixed in position by a single catgut stitch, the next couple of inches of catheter are buried in the intestinal wall by a continuous in-folding stitch, and the proximal end is passed through a hole in the omentum, as described by Mayo,[5] before being brought out through the abdominal wall. To the end of the catheter a long tube is attached to drain into a bottle beside the bed."

At frequent intervals 6 to 10 oz. of bicarbonate of soda solution are run into the intestine, the end of the tube then being immediately depressed and replaced in the receptacle so that the toxic intestinal contents are diluted and their escape by siphonage encouraged. The outflow from this tube can be completely controlled and, as soon as it ceases to be the dark foul-smelling fluid characteristic of intestinal obstruction, the tube can be clamped in the intervals of being used as a means of introducing a soda and glucose solution. In a week or ten days the catgut stitch holding the catheter in situ is absorbed and the catheter is then removed—in no single instance in my experience has there been any subsequent escape of intestinal content, and thus no necessity for further operation.

Notes of Two Cases.

The following notes of two cases will serve to illustrate the types of cases in which I have employed the method, and will, I hope, demonstrate its utility. One case was almost desperate, whereas in the other I might describe the use of the method as prophylactic, as by it I believe the advance of the paretic distension of the gut was controlled, and the development of what may be termed a "vicious circle" obviated.

Case 1.—A man, aged 60, was admitted to the Royal City of Dublin Hospital on Oct. 17th, 1924. He stated that he had been in failing health for some time; he had lost his appetite and suffered from marked constipation for some months; there had been no diarrhœa and he believed his motions had not contained blood or slime. Two weeks before admission he complained of a "soreness" in the left lower abdomen; this had gradually increased, culminating in an acute attack of pain three days previously. Since the onset of the acute pain he had vomited at frequent intervals, and could not retain even water taken by mouth; the vomit was dark and foul-smelling; his bowels had not moved for four days. Examination revealed a very grave state of affairs. His aspect was very bad, blue and pinched, and his general condition such that the clinical clerk described it in his notes as "collapsed, in extremis." The tongue was dry; temperature 98·8° F., pulse 110, but so weak and irregular that no reliance could be placed on the count. The abdomen was distended, distension being chiefly marked in the hypogastric region, while respiratory movement was confined to the upper abdomen; on palpation there was but slight tenderness and no rigidity in the upper abdomen, but both were marked below the umbilicus, and especially in the left iliac fossa; the presence of free fluid was easily demonstrated in the flanks. Rectal examination revealed the presence of marked tenderness and the characteristic "doughy" feel, associated with pelvic peritonitis; the rectum was empty. It was decided to operate as a forlorn hope. The abdomen was opened by a right paracentral incision below the umbilicus three-quarters of an hour after his admission. Immediately the peritoneum was incised foul-smelling pus escaped; everywhere in the lower abdomen the coils of intestine were acutely inflamed, dilated, and bathed in pus; there were no limiting adhesions. A hand was passed into the pelvis and a large quantity of very foul-smelling pus welled up; the appendix was examined and was obviously not the source of the infection, but on exploring the left iliac fossa a hard, irregular mass fixed to the brim of the pelvis was felt in the pelvic colon—a carcinoma or a diverticulitis which had perforated. A large tube was placed in the pelvis, both flanks were drained through stab wounds, and a left inguinal colostomy performed through a separate incision. A jejunostomy as above described was done into a dilated loop of the small intestine as high up as possible, and the patient returned to bed more dead than alive. His condition during the next three days was such that his death was hourly expected; his extremities were cold and clammy and the pulse at times imperceptible. The jejunostomy acted well; he received 8 oz. of soda bicarb. solution through it every two hours, and a great quantity of dark fluid drained away; vomiting ceased on the day following operation and fluids were give freely by the mouth from that time onwards. Hiccough persisted for several days after the vomiting had ceased. Fæces began to come from the colotomy opening on the third day. On the fourth the fluid from the jejunostomy tube became clear and, at the same time, his general condition showed a marked change for the better. The administration of the soda and glucose solution by the tube was continued for three more days and, in the intervals, the tube was clamped. His condition from the fourth day on gradually improved; the discharge from the drainage openings decreased and finally ceased. The jejunostomy tube was removed on the eighth day and no leakage of intestinal contents took place. Finally he was discharged on the thirty-first day in quite fair condition.

I have performed jejunostomy on two other almost identical cases of septic peritonitis, due to infection from tumours of the pelvic colon. One died and the other made a good recovery, although for the first two days following operation he was almost pulseless, intensely toxic, and apparently moribund.

CASE 2.—A boy, aged 16, was sent to the Royal City of Dublin Hospital on the evening of Jan. 6th, 1925, by Dr. P. Gavin of Moynalty. He stated that on the night of the 3rd he was seized with sudden severe pain in the right lower abdomen and vomited a great deal; the pain continued for two days but had eased off somewhat during the 24 hours preceding admission, being to some extent replaced by a "soreness" across the whole lower abdomen; he had vomited three or four times each day, and the bowels had not moved since the morning of the 3rd; there was some pain on micturition. On examination his aspect was moderately good, face flushed and anxious but not pinched; the tongue was furred and moist, temperature 102° F., pulse 112. The respirations were almost entirely thoracic; the lower abdomen was distended, the upper limit of distension being quite sharply marked at the level of the umbilicus; he was tender all across the hypogastrium, especially so in the right iliac fossa. Rectal examination confirmed the diagnosis of pelvic peritonitis and an operation was performed immediately through a right paracentral incision and revealed a diffuse purulent peritonitis of the lower abdomen. The coils of intestine in the pelvis were intensely congested and dilated, and lay in a bath of pus. The intensity of the congestion and the quantity of purulent exudate gradually diminished as the abdominal cavity proper was reached, so that the coils immediately underlying the umbilicus were dilated but not congested. A perforated pelvic appendix, gangrenous in its middle third, was removed; a large tube was placed in the pelvis and a jejunostomy performed into one of the dilated loops of the small gut, lying just above the level of the umbilicus. Instructions were given to place the patient in the Fowler position and to run six ounces of soda solution through the jejunostomy every four hours, the tube in the interval to to be left unclamped and draining into a bottle beside the bed. Rectal salines were also ordered. The conditions found at operation in this case were such that I gave a very guarded prognosis and anticipated a very stormy convalescence, so I was more than pleased next morning to find the lad looking well and to hear that he had not vomited since the operation. The tube was working well, a good quantity of dark fluid escaping; his temperature had fallen to 99° and pulse to 100. It is unnecessary to give details of the convalescence; suffice it to say that he steadily improved from day to day, the outflow from the tube becoming clear in 24 hours and the tube itself coming away on the seventh day, no fistula resulting. He finally made an excellent recovery although his discharge from hospital was delayed until the fortieth day owing to the development of a small secondary abscess in the right iliac fossa, which discharged through the scar of the original drainage opening.

Three other cases of diffuse peritonitis originating in the pelvis and extending into the abdomen proper were similarly treated and made good recoveries. In two the cause of infection was a gangrenous appendix, and in the other a rupture of a pyosalpinx. I have also employed jejunostomy in the following cases. (1) Pelvic peritonitis due to a gunshot wound traversing the pelvis and puncturing the rectum in two places. This man made a rapid recovery, the peritonitis not extending. (2) Acute intestinal obstruction by a band. This man was intensely toxic and great quantities of dark foul-smelling fluid drained from the tube for four days. After that time recovery was uneventful. (3) Acute pneumococcal peritonitis. This patient died from a general pneumococcic septicæmia.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ELECTRO-THERAPEUTICS.

A MEETING of this Section was held on April 17th, Dr. STANLEY MELVILLE, the President, being in the chair.

The Organisation of a Light Department for Surgical Tuberculosis.

Sir HENRY GAUVAIN read a paper on the organisation and work of a light department in a surgical tuberculosis hospital. He said that though he had used heliotherapy for some years, it was only since the war that a light department had been established in the hospital of which he had charge at Alton, and that was owing to the munificence of Sir William Treloar. He explained that he meant by "light treatment," treatment by light produced artificially as opposed to sunlight; he objected to the term "artificial sunlight." Theories which had been advanced as to the biological action of light were contradictory, sometimes confusing. He was convinced as to the value of light in surgical tuberculosis, but this form of treatment was very expensive, as large amounts of current were consumed, the services of skilled electricians must be secured, experimental work must be done, numerous accessories purchased, and a staff of nurses specially trained must be maintained. An equipment for giving light treatment was urgently needed, especially for cases of lupus. At Alton there was already an admirable generating plant. and the resident engineer skilfully adapted the new plant without extra expense. Finality in this matter had not yet been reached, and he believed much that was important would be discovered in the near future, therefore room should be left for possible modifications. Accordingly the ward for this work was a wooden structure, placed quite near to the power-house, to save cost of cable, and risk of fire was reduced by covering floor and walls 4 feet high with asbestos. There were two cables, one to convey a current of 70 volts, the other one of 110 volts. He took as his model the Finsen Institute in Copenhagen, which he visited twice and for which he had unstinted praise. There the lamp used for general light baths and local treatment was the carbon arc lamp. Lupus remained the most common form of tuberculosis treated. A highly-educated woman came from the Copenhagen institution to Alton to instruct the nurses there, and remained six months. At Alton eight ambulant cases could be treated simultaneously by means of the 75-ampère carbon arc lamps, and there were two water-cooled carbon arc lamps for local treatment.

The Use of Ultra-Violet Rays.

Sir Henry Gauvain said he also made provision for testing and employing any other form of radiation which seemed to promise success, and much attention had been given to the subject of ultra-violet radiation. The value of this, especially in rickets, had been amply demonstrated; and it raised the bactericidal power of the blood. The tendency nowadays was to use, in increasing degree, the short rays of the spectrum, but many "artificial sun" lamps were rich in rays not to be found in the solar spectrum. He had used mercury-vapour, tungsten arc, iron arc, and other lamps, also numerous electrodes, and they were serviceable for certain local conditions, but in a general way for surgical tuberculosis they had not come up to his expectations. He preferred the Finsen lamps. Clinical experience still remained the most reliable guide. The tendency to employ short wave radiation indiscriminately was not without danger. In acute neuritis of undiscovered cause, however, these rays quickly produced a very striking relief.

On the physical side it was possible to produce an almost infinite variety of radiant energy, but there was still so much to learn concerning its biological effect that there was need of skilled laboratory workers in connexion with light departments. In such a department there must be complete and responsible supervision during the treatment; all the work was visible to the charge nurse, and there were no cubicles, though privacy was secured when certain areas of the body were being treated. At the conclusion of treatment the whole department was cleaned out, and all lamps, lenses, and compressors received careful attention. At the present time 28 patients were having arc treatment each day, and 56 persons had light baths every alternate day. Goggles were worn, each patient having his or her own. Water was drunk during the treatment. The exposure was half an hour for new patients, and was increased to a maximum of two and a half hours. It induced free perspiration, and at the conclusion the ambulant cases had a shower-bath and rub down. The patient's head was protected from the heat by asbestos masks. For local treatment the part concerned was first exsanguinated by means of compressors, and no further treatment of the area was carried out until the local reaction had subsided. Most of the patients had graduated seaside baths at Hayling Island, and the beneficial effect of this was very marked.

For surgical tuberculosis Sir Henry Gauvain regarded the light treatment as an accessory, the success depending on the skill with which it was blended with the other means. For this form of tuberculosis the air-cooled mercury-vapour and tungsten arc lamps were not so valuable as the carbon arc lamps, and their value diminished after a few applications. They had been found to be good for sinuses, suppurating and discharging glands, scrofuloderma, &c. The water-cooled iron arc lamp was good for local lesions, and it had the merit of being cheap. Infra-red radiations were of limited value, but in patients whose blood possessed high bactericidal power they hastened cure. Sir Henry Gauvain said he was now engaged in perfecting a lamp designed for giving light treatment to patients who could not be brought to the hospital. Some of the requirements were that the lamp should be readily portable, simple in application, and adaptable to the ordinary wall-plug for electrical supply. He said he felt grave misgivings as to the use of a powerful source of ultraviolet light in the hands of the inexperienced. Certain disease conditions derived greater benefit from one form than from others, and some only received the maximum help from both forms of radiation, supplemented by physical aids to cure. Work was now being done at Alton which, without the aid that the newly-installed department gave, could not have been done at all. He had frequently cut out portions of tissue which had been irradiated and shown that the tubercle bacilli in them were dead.

Selection of Apparatus for Producing Artificial Sunlight.

Dr. G. Murray Levick said the time had not yet arrived for laying down hard-and-fast rules on this subject, as experience was brief. "Artificial sunlight" should be understood to mean the application to the body of rays such as were found in sunlight, but not necessarily in the proportions occurring in nature. By using the mercury-vapour lamp with the long-ray lamp he had obtained better results over a large range of cases than by the use of the open arc lamp. He had successfully used the latter with carbons which were impregnated with nickel, especially for cases of general debility without apparent cause, neurasthenia, and chronic rheumatism. But the open arc lamp with carbon terminals did not give such good results in the case of rickety and tuberculous children as did the mercury-vapour combination, and the latter permitted of accurate dosage, an important matter, as elderly subjects with rheumatoid conditions showed an extreme sensitiveness to light, and experienced a reaction, as evidenced by aching pains, headache, and a slight rise of temperature. Recently there had been placed on the market self-exhausting tubes, and it was not yet known how long they would last. A 2000-candle power mercury tube sufficed for all general purposes. The chief faults were inaccessibility of the reflector and the difficulty of accurate focusing; he was designing an apparatus in which these would be overcome.

He had found that the red rays were of great value in promoting nutrition and the power of local repair, probably through local stimulation of the sympathetic nerves. These rays penetrated very deeply, and quickly promoted growth of muscles. Heat rays were interrupted by water. A disadvantage of the mercury-vapour lamp for general use was that, on account of the intensity of the radiation, it required skilful handling. It was most important that the patient should be stationary during the application, so as to preserve a uniform focus. He pleaded for exactitude in the administration of radiation. He agreed that the arrangement, organisation, and working of the Copenhagen institution were masterly.

Dr. P. R. Peacock referred to the work which had been done by Prof. Russ and himself on the physics of ultra-violet irradiation. He said that pigmentation frequently resulted from exposure of the skin to the rays. It was agreed that there were unaccountable variations in the response of different people when exposed to the same kind of treatment, some pigmenting, others merely freckling. Clear skins fluoresced better than did dark ones. Certain parts of the body were fluorescent; sweat and blood were non-fluorescent. Sebum was the most brilliantly fluorescent, and melanin absorbed the whole visible spectrum. From the ultra-violet point of view, fluorescence seemed to be a protective phenomenon. Skin which had been treated with vaseline withstood three and a half times the radiation of normal skin before showing reaction. Pigmentation occurred only as a result of considerable exposure, and it might be taken as an indication that fluorescence had failed to protect the tissue. Hence if application of the treatment could be made without producing pigmentation the effect might be much better, as pigmentation protected the skin against the action of the very rays which it was sought to influence it by.

MANCHESTER MEDICAL SOCIETY.

A meeting of this Society was held on April 1st, Prof. G. R. Murray, the President, being in the chair. Dr. D. E. Core opened a discussion on

Encephalitis Lethargica.

He began by describing a typical case of average severity in a man of 24, and then dealt with certain symptoms in detail. As regards the diagnosis of encephalitis lethargica, he said it was important to remember that often enough the condition escaped recognition as an illness by the patient and his friends; it might only be revealed as such in the light of the after-course. The idea of establishing a diagnostic scheme based upon symptoms was in his mind untenable, and the present-day tendency to do so was responsible for the number of erroneous diagnoses. Apart, however, from objective signs of implication of the nervous system, he had been increasingly impressed by the interesting relationship between the symptoms and the patient's consciousness. In normal life there was a reasonably close parallelism between objective behaviour and the personality of the individual; a man who acted in an uncontrolled way usually showed signs of mental uncontrol; one who seemed to be profoundly unconscious was as a rule unconscious; and a delirious patient was not in general aware of his surroundings. In encephalitis lethargica, however, this association did not appear to obtain. The most restless and uncontrolled patient was quite commonly capable of giving a remarkably clear and logical account of his sensations without any evidence of psychical uncontrol; it was notorious that the patient somnolent to the point of coma was not only often, but was usually able to answer questions and give information demanding considerable concentration; and the same phenomena were to be observed in the delirious patients. Furthermore, the ability to memorise subsequently events occurring in their environment at such times was considerable. In other words, instead of the normal association between the psychical state and the somatic symptoms, there was a dissociation; a dissociation which was anatomical rather than psychical and which, in his mind, was the most characteristic feature of the disease under discussion. The same principle was at work in the frank emotional uncontrol that was liable to affect children as an after-state and the somatic uncontrol in the young adult with symptomatic paralysis agitans. From the standpoint of diagnosis this dissociation was, in his opinion, of greater value than objective signs of cerebro-spinal implications.

Dr. W. **ST. CLAIR MCCLURE** said that encephalitis lethargica was an infectious disease spread by "carriers." The organism responsible was universally distributed, but happily the majority of people were immune to its attack. All ages were liable to attack, but the incidence fell specially heavily between the ages of 10 and 20 years. Males and females were about equally attacked, and there was no special preponderance of cases in any one particular occupation. Bad environment appeared to predispose to an attack. In a series of 224 cases in 1924, 20 per cent. died, and after 12 months 20 per cent. had apparently recovered and 60 per cent. had residua of some kind, two-thirds of which were of a Parkinsonian character. Similar figures for 50 cases which occurred in Manchester in 1920–21 were: Mortality-rate 56 per cent., recovery-rate (three years after onset) 14 per cent., and incapacity-rate 30 per cent. Taking into consideration wrong diagnoses and non-recognised cases, 15 to 20 per cent. probably represented the recovery-rate, though it differed in different epidemics. The prognosis in any individual case was guess-work, but it was a hopeful thing to know that complete recovery was possible in cases which at first appeared hopeless, and it was to be noted that all who did not recover were not totally incapacitated. In many the disease process came to a standstill and a useful and more or less happy existence was possible.

Hiccup.

Hiccup might occur as one of the symptoms of encephalitis lethargica, and one must suppose that it might be the one and only sign of the disease. Epidemics of hiccup and encephalitis, however, did not as a rule run concurrently. In Manchester, in 1924, a hiccup epidemic preceded the encephalitis epidemic. In December, 1923, and January, 1924 there was a generalised epidemic of hiccup in the city. The attacks consisted of persistent hiccup lasting three to ten days, unaccompanied in the majority of cases by other symptoms. Some few exhibited drowsiness. The sufferers invariably recovered without sequelæ, and inquiry 12 months after had not so far resulted in the discovery of any post-encephalitis signs amongst them. In the investigation of cases of encephalitis lethargica special inquiry was made amongst 1200 contacts for a history of hiccup. Only two were discovered. The households attacked by encephalitis lethargica were not those attacked by hiccup. Amongst the encephalitis lethargica patients hiccup was one of the symptoms in about 3 per cent. There was therefore no evidence favouring the view that the two diseases were associated, though such a possibility was not excluded. Influenzal cases had not given rise to encephalitis lethargica, nor had cases of the latter disease given rise to influenza. A study of the epidemic waves of influenza and encephalitis in Manchester showed that there was no correlation in point of time between the two diseases and provided no evidence in support of the contention that they were associated in any way one with the other.

Pathological Aspects.

Prof. J. H. **DIBLE** said that, speaking as one who saw the disease from the pathological side, he was in full agrement with the previous speakers as to the difficulties in clinical diagnosis. The first three cases in which he was called upon to do post-mortems turned out to be tuberculous meningitis. He wished to draw the attention of the Society to the experimental pathology of the disease. At the onset of its epidemic phase, analogy with poliomyelitis suggested that it might be transmissible to apes and investigated upon the lines so successfully followed by Flexner and his associated workers in the latter disease. Early experiments, however, particularly of McIntosh and Turnbull in this country, failed to infect these animals, and it was not until 1919 that Strauss, Hirschfeld, and Loewe reported successes from America. These workers then reported further successes with nasopharyngeal washings and cerebro-spinal fluid, as well as brain material, as the source of the infecting agent, and they claimed that the rabbit and not the monkey was the animal of choice for this work. Early in 1920 Levaditi and Harrier claimed to have transmitted the disease to rabbits, and about the same time McIntosh published an account of similar successful inoculation of monkeys in series, and from monkey to rabbit. The speaker himself had since 1920 been attempting to convey the disease to the lower animals, and gave details of many attempts, using material derived from ten cases of the disease, to transmit the infection to rabbits. These invariably failed whatever type of material was used as inoculum and by whatever route the inoculation was made. Attention was drawn to the existence of two schools, the one claiming that production of the disease in animals was readily enough accomplished to be used as a diagnostic measure with the cerebro-spinal fluid, whilst the other school, of whom Levaditi was the protagonist, claimed that the disease was definitely inoculable but only with difficulty, and that success was rare. Prof. Dible's own experiences had been entirely negative. Recently Flexner, whose authority in this type of work was very great, had published the results of a very large series of attempts which he had made in conjunction with Amos. All material from cases of encephalitis had failed to infect: a positive result was obtained in one instance, but this was with cerebro-spinal fluid from a case of cerebral syphilis and not one of encephalitis at all. Such results called into question again the validity of all published positive results. The matter was one of great difficulty, and complicated in many ways, one of the most confusing questions being the relationship of the encephalitis produced in animals by certain workers to that which the herpetic virus of Grütner was capable of setting up. Much more work was required before the matter could be regarded as settled, but in the opinion of the speaker the claim to have transmitted the disease to animals was as yet unsubstantiated.

Dr. C. J. C. **EARL** spoke of the cases under his care in Monsall Hospital. He agreed with the previous speakers as to the difficulty of diagnosis. Out of 16 cases admitted as encephalitis lethargica 11 were proved to be other conditions, including tuberculous meningitis, brain abscess, and brain tumour. Some of these cases were impossible to diagnose on physical examination alone. He had seen the typical dissociation of which Dr. Core had spoken, in a case of a cerebral abscess situated in the region of the basal ganglia. One case was admitted certified as mumps which proved to be encephalitis with parotitis. In three out of five of the more acute cases admitted herpes labialis was present. In one of these cases the sister of the ward also developed herpes labialis though without any nervous signs. He would be interested to know whether she should be regarded as suffering from the disease in a latent form or, on the other hand, as immune to it. One of the acute cases had shown excitability to a marked degree. He mentioned one case of inversion of sleep rhythm. This case—a child—was more intelligent and cunning during the night than in the day time. He also wrote a much clearer hand at night.

Reviews and Notices of Books.

Chronic Epidemic Encephalitis.

By August Wimmer, M.D. With Preface by Sir F. W. Mott, K.B.E., M.D., F.R.C.P. Lond., F.R.S. London: William Heinemann (Medical Books), Ltd. 1924. Pp. 335. 21*s.*

P. M. Latham, in his lectures on subjects connected with clinical medicine, wrote: "In chronic disease we see only what it has done, not what it is doing; in acute disease we see both." Acute epidemic encephalitis is showing us what it has done in its chronic manifestations. It is now apparent that the acute symptoms of the disease may (1) subside altogether, (2) merge into a chronic form, or (3) chronic symptoms may supervene after a period of remission. It should be added that in a large proportion of cases the acute attack of encephalitis passes unrecognised or is concealed under the term of "influenza" or "febricula." Transient diplopia is frequently associated with the acute stage.

Dr. Wimmer, who is professor of psychiatry in Copenhagen University, was, he tells us, initiated into English neuropathology by Horsley and Beevor. He has produced an admirable book on the chronic manifestations of epidemic encephalitis, with examples of clinical cases that have been under his observation. The work on this subject, owing to the comparatively recent recognition of epidemic encephalitis, is of necessity incomplete; it is no disparagement to state that in its present form his book must be regarded as an interim report upon the chronicity of epidemic encephalitis. The pathology of the chronic disease is not fully worked out; the few inoculation experiments made on rabbits are noted with proper diffidence, and as regards course and prognosis of the malady, the author states that no reliable forecast can be given in the concrete case, the prognosis being mostly guess-work. Until the lapse of time has allowed these matters to be adequately valued, the neurologist will find Prof. Wimmer's work a useful guide and aid in checking his own studies of clinical cases.

Prof. Wimmer considers the chronic forms of epidemic encephalitis under several heads. The account of psychotic disturbances agrees closely with the British and French descriptions. Stress is laid upon the changes in moral character and conduct displayed by children, upon the nocturnal type of disturbance, and upon the well-recognised fact that it is rare to find such coarse moral deterioration in adults as in youths and children. Disorders of sleep in both children and adults, including the troublesome insomnia, are described. Under the classification of vegetative symptoms, such phenomena as salivation, general or localised perspiration, vasomotor disturbances, obesity, and emaciation are noted. The author draws attention to the oscillations in temperature that are seen occasionally in the chronic forms of disease; he advises that the morning and evening temperatures should be taken daily. The main features of chronic encephalitic Parkinsonism, "paralysis agitans sine agitatione," are given. Prof. Wimmer is unable to dismiss the supposition advanced by Souques, Netter, and others that the "classic" paralysis agitans may be, often or perhaps usually is, of an encephalitic origin. It would be interesting to learn whether symptomatic paralysis agitans is of such frequent occurrence in Denmark as Souques, Naville, Bing and Staehelin, and others find it to be on the Continent.

A large section of the book is devoted to intermediary types. Under this heading Prof. Wimmer has grouped a number of clinical manifestations. It is interesting to note, having regard to the frequency of involvement of the ocular nerves in the 1918 epidemic, that the author finds while in some few cases the eye symptoms of the initial stage may persist during the further course of the encephalitis, they will, as a rule, disappear. Involvement of the optic nerve was detected in seven cases, which is exceptional. Some patients relapsed into lethargy. Several cases presenting epileptic seizures are described; it is possible that some, if not all, of these were examples of true idiopathic epilepsy; indeed, after reading this part of the book we are left with an uneasy impression that Prof. Wimmer in his search for intermediary types has thrown his net a little too wide. Extra-pyramidal hyperkinesia, under which term the author includes tremors, myoclonus, choreiform movements, and athetoid (torsion) movements, completes the classification of chronic epidemic encephalitis. There are interesting chapters on diagnosis, pathogenesis, and pathophysiological mechanisms. The author inclines to the view that the chronic manifestations of epidemic encephalitis are due to persistence of the causal virus in the human organism.

Prof. Wimmer writes in excellent English and his book is well illustrated by photographs and photomicrographs.

Diseases of the Nose, Throat, and Ear.

Fifth edition. By E. B. Gleason, M.D., LL.D., Professor of Otology, Medico-Chirurgical Graduate School, University of Pennsylvania. London and Philadelphia: W. B. Saunders Company. 1924. Pp. 660. 20*s.*

This text-book, which is of the type intended for students and general practitioners, is full of valuable instruction and gives evidence of the author's wide practical experience. The appendix on formulæ contains an unusual feature, a full description of the action and method of use of the more important drugs, which will be found very useful. The section on diseases of the ear is particularly thorough and good. In some places the work suffers from a lack of orderly arrangement; for instance, otosclerosis is so mixed up with middle-ear catarrh that a clear picture of the disease and its treatment is unobtainable. More space could be gained by the omission of some operations which are now little used; for instance, a full account is given of the operation of severing the incudo-stapedial articulation, and mobilising or extracting the stapes, of which the author says that he performed it a number of times some years ago. The description of paralyses of the larynx fails to give a clear idea of their ætiology, so valuable in the diagnosis of various diseases, and does not note the fundamental distinction between the functional adductor paralyses and those resulting from organic lesions of the nerve-tract. Indeed, adductor paralysis of one vocal cord is described, with no hint that it is uncommon; and of Semon's law it is only said that "in all progressive lesions of the centres or trunks of motor laryngeal nerves the abductors are more frequently affected than the adductors," surely a very insufficient statement of the case. The illustrations, on the whole, are not worthy of the text.

Collected Papers.

Published Papers by Members of the Staff of the Middlesex Hospital Medical School, 1923–24.
Collected Papers of the Department of Physiology, University College, London. Vol. XXII. 1924.

The collection and publication of papers by groups of workers in the same institution is undoubtedly a valuable method of recording research work, but the reproduction of the essays is attended with one drawback, only to be avoided by expense that would not be warranted. In both of these volumes reprints of widely different sizes have been bound together, with curious heterogeneous results; some of the reprints have required awkward cutting or folding; the association of coloured covers of individual papers, often of contrasting and violent hue, does not please the eye, and indexing has proved impossible.

The material in both these heterogeneous volumes is really valuable, records from the Middlesex Hospital of important work on the effects of radium and X rays on cancer being especially noticeable. The measurement of radiations on the one hand and their effects on general metabolism on the other form the subject of several communications. Biochemical investigations on the toxæmias of pregnancy, certain aspects of the preparation of insulin, and interesting work carried out on dental caries, with particular reference to the *Bacillus acidophilus odontolyticus*, are other examples of recent work emanating from this hospital.

Of the collected papers of the physiological department of University College an assortment of reports of researches on questions of muscular activity forms a large part, and includes the Nobel lecture of 1923 by Prof. A. V. Hill. The other main interest lies in the work on vitamins, especially the fat-soluble factor; investigations into the properties of cod-liver oil and into the production of rickets in certain animals such as cows and pigs form an important part of the work carried out during the past year. The scientific value of the papers published in both these volumes need not be emphasised, for it is unquestioned. Several of them we were privileged to publish in our columns, and on others we have had occasion to comment on their appearance in special journals. Their value as permanent records of the achievements over a given period of the staff of an institution would be so much enhanced by better format that it is impossible not to regret their appearance.

The orderly volumes issued by certain institutions across the Atlantic form a striking contrast to these publications; they are doubtless far more costly.

PÆDIATRICS.

The Practice of Pediatrics. Third edition. By C. G. KERLEY and G. W. GRAVES. London and Philadelphia: W. B. Saunders Company. 1924. Pp. 922. 45*s.*

THIS volume is the outcome of a thorough revision of Prof. Kerley's well-known text-book by the author in collaboration with Dr. G. W. Graves. The amount of new material which it contains is large in proportion to the very moderate increase in size, owing to the elimination of a number of the older articles. The new edition presents a comprehensive survey of the subject, and includes the infectious fevers and also many of the ailments of childhood which are commonly classed as surgical.

The chapters concerned with the infant have been revised and enlarged; they contain a wealth of sound advice as to general management, but the methods of milk modification which are recommended have the drawback of being somewhat complicated, and on the whole more suitable for an institution than for the practitioner. Night feeding is advocated during the first three months, and the addition of cereals from the fifth month. The statement "that starch may be digested by the youngest and most marasmic infant has been proved" may be strictly correct and yet be a source of danger if adopted too freely as a principle in infant feeding.

Considerable addition has been made to the section on gastro-intestinal ailments, which now occupies a large proportion of the book. The authors attach great importance to developmental abnormalities of the alimentary tract in the production of malnutrition and disease, and illustrate their description of them by a series of excellent radiograms. The principles of dietetics in the years following infancy are presented clearly; excessive consumption of milk is regarded as the most frequent source of digestive troubles during these years. Fewer changes have been made in the chapters on respiratory diseases, but the section on asthma has been re-written, and includes an account of protein sensitisation. The authors have not modified their view of the treatment of empyema, and adhere to the opinion that aspiration is never to be looked upon as a substitute for incision. Among other additions will be found a description of encephalitis lethargica; the sequelæ hardly receive due recognition of their importance to pædiatrics, being summarised in a few lines without any reference to disturbances of sleep. An article entitled the Suboxidation Syndrome contains an interesting review of a group of symptoms corresponding fairly closely to those which are associated with the term vagotonia.

The appearance of the new edition brings this work fully up to date; it is clearly written and well indexed, and is likely to increase the popularity of the former editions.

Safeguarding Children's Nerves. By J. J. WALSH, M.D., Professor of Physiological Psychology, Cathedral College, New York; and J. A. FOOTE, M.D., Professor of Diseases of Children, Georgetown University Medical School. London: J. B. Lippincott Company. Pp. 272. $2.00 (9*s.*).

THE authors of this book have attempted to provide parents and others who are interested in child welfare with a manual of child management directed particularly to the production of a stable nervous system. In a large measure they have succeeded; the book is easily intelligible and free from fads, and contains much sound advice presented in a homely and convincing style. Fresh air, exercise, and facilities for spontaneous play are stressed throughout the work as the fundamental requirements of a healthy environment; the failure to provide them, and their replacement by unsuitable occupations—the "menace of the movies" in particular—are regarded as the most frequent causes of nervous instability in the child. The authors' attitude towards discipline is balanced and reasonable; while opposed to unnecessary restrictions and "don'ts" they deprecate the present tendency to dispense with penalties, and consider that corporal punishment calmly administered is frequently preferable to any of its substitutes.

The parts of the book which deal with the attainment of a healthy environment are sound and helpful, but on the more controversial ground of causation the authors may be accused of overstating their case. The chapter entitled the Bogey of Heredity does not add to the value of the book, and is likely to mislead many of its readers. The careful research of Dugdale and Goddard into family histories is referred to with scant respect, and the impression is given that their conclusions are discredited. Arguments based on Mendelian laws are brought forward which may be applicable to the transmission of mental defect, but it is not made clear that there is no evidence of their application to the transmission of neurotic tendencies, with which the work is principally concerned. The chapter on defective children is admirable, and contains most valuable advice, which is too seldom given to parents, on the serious effects of retaining these children in the home.

Essentials of Infant Feeding. By E. A. BARTON, Medical Officer to the Child Welfare Department, University College Hospital. London: H. K. Lewis and Co. 1925. Pp. 80. 3*s.* 6*d.*

THE object of this little book is to initiate the student into the technique of an infant clinic. The material is highly condensed, and is rightly presented in a somewhat dogmatic form. It falls into three divisions, dealing with breast-feeding, milk, and artificial feeding. Dr. Barton is to be congratulated on having achieved not only lucidity, but simplicity, in the last two sections of the book, and the student will be able to obtain from it a clear idea of the rationale of infant feeding, without being bewildered by the elaborate formulæ by which this subject is so often complicated. The extent to which he should put his trust in calories is discussed in an easily intelligible manner, as are many of the other problems in which theory and practice require some mutual adjustment. This book should fulfil admirably the purpose for which it was written.

ULTRA-VIOLET RAYS IN THE TREATMENT AND CURE OF DISEASE.

Second edition. By PERCY HALL, M.R.C.S. Eng., L.R.C.P. Lond. With introductions by Sir HENRY GAUVAIN, M.A., M.D., M.C. Camb., and LEONARD E. HILL, M.B. Lond., F.R.S. London: William Heinemann (Medical Books), Ltd. 1925. Pp. 114. 7*s.* 6*d.*

WE have ample proof that artificial light rays supply us with an admirable weapon in so far as the fight against surgical tuberculosis, lupus, and rickets is concerned. Many lamps have been placed on the market, some of which do and some of which do not give off ultra-violet rays. Unfortunately, many inaccurate and misleading impressions seem to have become settled in the lay mind. Among others, that treatment by such lamps is a simple and harmless proceeding, whereas it requires the supervision and guidance of an expert. It is to remove these false impressions that this book has been published, and the author's testimony is supported by introductions from Sir Henry Gauvain and Dr. Leonard Hill, who have done so much of the pioneer work on this subject in this country.

Dr. Hall has had much practical knowledge of the uses of lamps for artificial light treatment and gives a general survey of his results in treatment of various diseases. His book has been so well received that a second edition has appeared seven months after the first. The results obtained by Dr. Hall in treatment of such various maladies as rheumatoid arthritis, gout, osteo-arthritis, lumbago, sciatica, neurasthenia, pulmonary tuberculosis, chronic dyspepsia, and high blood pressure are very interesting. He is careful to point out that he uses artificial light rays merely as an adjuvant. In fact, he would appear to make as much use of diathermy as he does of ultra-violet rays. No doubt, although he does not say so, he has used rest, diet, change of scene, and other valuable factors in treatment.

We all know that those who can afford it pay yearly visits to sunny climes for the alleviation of such diseases as Dr. Hall enumerates. This, in itself, is some confirmation of the claims that he puts forward. Those remaining at home are robbed of much of the sunlight there might be in fine weather in winter by the smoke nuisance and the prevalence of fog. It will be a boon if artificial light rays, properly and skilfully controlled, prove to be a substitute for the sun during the winter darkness.

TEXT-BOOK OF OPHTHALMOLOGY.

Eighth edition, revised. By Hofrat ERNST FUCHS, former Professor of Ophthalmology in the University of Vienna. Authorised translation from the twelfth German edition, with numerous additions by ALEXANDER DUANE, M.D., Surgeon Emeritus, Knapp Memorial Hospital, New York. London: J. B. Lippincott Company. 1925. With 455 illustrations. Pp. 997. 42*s.*

THIS is practically the same book as the seventh edition, published in 1923. So slight indeed are the alterations that the paging is unaltered, and the index to the seventh edition serves equally well for the eighth. There are a few additions of small importance and some new illustrations, while some of the old ones have been redrawn. Thus the diagram of the nerves and centres constituting the motor apparatus of the eye is elaborated so as to include the cortical motor centres and the labyrinth of the ear. In the section dealing with operations an improved method of blepharoplasty for the lower lid is described, but unfortunately, owing to a misprint, the description is wanting in lucidity. Perhaps the most notable addition is the recognition of recession as an essential part of the operation of tenotomy of an internal rectus. Without this or some equivalent procedure the operation is only too likely to cause a divergence, if not as an immediate result, at some later period.

The continual demand for this book, one of the best known of the larger ophthalmological text-books, is a proof of its popularity on both sides of the Atlantic.

JOURNALS.

JOURNAL OF INDUSTRIAL HYGIENE, January, 1925.—In this issue the Relation of Organic Dust to Pneumonoconiosis is discussed by H. R. M. Landis. The author points out that a mistake is made when the well-known damage caused by inhaling inorganic dusts, notably silica, is extended to organic dusts. No evidence exists to condemn organic dusts. He obtained autopsy protocols on 50 persons who had never followed any other occupation than that of textile workers; in no case were there changes in the lungs comparable to those noted from exposure to inorganic dust. The findings and also the causes of death differed definitely from those seen, for instance, in the pottery industries. He concludes that organic dust has no power to establish the condition known as pneumonoconiosis. At the same time he allows that some organic dust gives rise to protein intoxication, such as asthma and threshers' fever.—An article of unusual interest is contributed from Moscow by I. Guelman on Industrial Poisoning by Arseniuretted Hydrogen. It is based on the occurrence of 12 cases treated at the Moscow Institute for Investigation of Occupational Diseases. Detailed observations are given, and the author shows reasons for holding that poisoning by arsine acts primarily and mainly by destroying and damaging red corpuscles; by liberating hæmoglobin and so causing hæmoglobinæmia; and from a consequent myelogenous reaction. The symptoms observed are due to these alterations in the blood interfering with the normal function of various organs. Thus jaundice and hæmoglobinuria follow from the hæmoglobinæmia, while the function of the liver is overstrained by the same condition. "The course of the disease is a convulsive struggle of the system to free itself of this ballast." Arsine passes through the alveoli of the lungs without damaging the cells; nor is there evidence that other cells except the erythrocytes are in any way damaged. When once the blood condition is remedied, the different organs recover entirely. The article is not only of interest in itself, but is an indication of the good work which is being done at industrial clinics in Russia.—J. A. Myers deals with the vital capacity of the lungs and its practical application. He presents a useful and well-written summary of work done by other observers on this subject, and also gives a valuable bibliography. February, 1925: The anatomical distribution of occupational cancers is dealt with by E. L. Kennaway, who gives valuable information as to the occurrence of cancer of the skin due to coal-tar products in various occupations, such as those of chimney-sweeps and shale-oil workers. The author gives special information obtained from the Registrar-General as to the distribution of cases of cancer of the skin in England and Wales. He concludes that cancer due to pitch and soot shows a considerable difference in anatomical distribution. Among pitch workers it occurs upon the head and neck, the cheek, lip, and eyelid, while soot in chimney-sweeps only affects the scrotum. In mule-spinners again, where oil is the offending material, the scrotum shows especial liability. Aniline workers are affected in the bladder. The author has made an intensive study of cases reported in literature, as well as a careful statistical presentation of all information he was able to obtain. The article is one of considerable importance.

THE LANCET.

LONDON: SATURDAY, APRIL 25, 1925.

THE PROBLEM OF THE MYOPIC CHILD.

IN his recently published book, "School Vision and the Myopic Scholar,"[1] Dr. JAMES KERR draws attention to an educational problem the solution of which has only as yet been just begun. We have blind schools for the "educationally blind," and in London we have "myopic schools" or "sight-saving classes" for high myopes and other children who, although they are certainly not blind, suffer from such defects of sight as render them obviously unfitted for the ordinary school routine. What we have not at present, either in London or elsewhere, is special provision for that large percentage of children, most of them low myopes, whose sight is in danger of being made worse as the direct consequence of the close application to books expected of them during their school years. Dr. KERR, who for many years organised the work of medical inspection in the London elementary schools, tells us that there are about 2000 children in London requiring education in the existing myope classes, but there are at least ten times that number who would benefit visually by a simpler sight-saving education than is afforded by any arrangements at present in force. The great majority of these are myopes of a moderate degree with a tendency for the myopia to increase under unfavourable conditions. The importance of this is shown by Mr. N. BISHOP HARMAN'S statistics,[2] proving that in later life myopes are liable to "failure in work" in direct proportion to the degree of their myopia, those engaged in clerical or other forms of close work being always far more subject to breakdowns than those of a similar degree of myopia not engaged in close work. What is not sufficiently realised is that the danger of myopia in childhood begins with comparatively low degrees. "Any child of 11 to 12 years of age," says Dr. KERR, "with myopia equal to four dioptres or more is likely to be harmed by further academic work in the sense of reading or writing, or fine work like drawing or sewing. These particular children are often precocious intellectually. They have gained a scholarship, their ages average 11½ years, and they must stay at school till 14 at the earliest; they have probably attained Standard VII., hence to remain at the primary school is merely marking time. On the other hand, they cannot be regarded as blind or semi-blind, and the myope schools are probably below their standard of scholarship."

What, then, is to be done with regard to the education of these children? As an immediate measure of protection, says Dr. KERR, every child with two dioptres of myopia by the age of 11 should be put under half-yearly reports, partly for safety and partly for parental education, and with -3 D. or more should be rejected for scholarships. Instructions to the teachers should distinguish between the slightly affected cases—"children for easy treatment"—who may be permitted to continue their studies under certain restrictions, the most important of which is the prohibition of all home-lessons—and those whose cases are more serious who should be recommended for oral teaching only. What is desired is an extension of the present system of myope or "sight-saving" classes to include as many as from 8 to 10 per cent. of the whole number of children in the school. In these classes the use of books, pens, paper, pencils, and slates of any kind is prohibited, and instead each child has a large blackboard on which he writes with chalk. On the other hand, for all lessons that can be learned by listening to the teacher the children in the myope class go into the ordinary school. A speciality is made of various forms of handicraft and most of the myopes are able to join with the other children in learning to dance and drill, though in the case of myopes exercises involving holding the breath, such as diving and swimming under water, or the "tug-of-war" are to be avoided. With regard to the less serious cases, Dr. KERR'S proposals will appear to some to be unnecessarily drastic. It may be true, as he says, that 50 per cent. of the present "standard" work is of scanty permanent life value; it may at least be true for the majority of the children, but to cut off such a large proportion of children as is proposed from all books might certainly bear hardly upon some, and Dr. KERR himself confesses that many of the best pupils in the present myope schools are almost marking time for the last two or three years of school life. The remedy appears to be, on the one hand, the establishment of classes for myopes in secondary schools, and, on the other, a careful selection of the low myopes needing special teaching. Would it not be permissible, for instance, to concede that any whose myopia was shown by medical inspection not to be increasing after, say, a year's probation might be restored to the book-reading classes? Such a proviso might make the proposed regulations more easy of acceptance both by teachers and parents, and, we may add, by ratepayers, for we must not forget that any extension of special classes must involve additional expense.

◆

DETERMINATION OF SEX.

THE mysteries of sex have a great fascination for the human mind, whether this be in the form of the natural or prurient curiosity of youth, the more anxious desire for information of a responsible age, or the efforts of the biologist to understand their bearings in natural law and evolutionary progress. Our daily journals have of late been regaling their readers with semi-bowdlerised versions of recently expressed views on the subject, from which it would appear that women may not only "have children at their desire," but—a matter about which the Psalmist maintains a modest silence—may have them, to order, of any sex that happens to suit their particular requirements of the moment. Such, at least, seems to be the physiological Utopia whose coming is dazzling the anticipatory imaginations of the general public. Fallacious theories of sex-determination, on which ineffective practice rested, have not been unknown in medical history, but the theory which is *sur le tapis* at present is said to be new, true, and therefore worthy of credence. We do not wish to throw dark doubt or suspicion on the simple faith that lies behind this claim, or to do more than suggest that it should be received with caution. So far as novelty is concerned, the views published a good many years ago by Dr. RUMLEY DAWSON (with a second edition in 1917) seem to be of an essentially similar nature: he was, we believe, the first to suggest that the sex of a child depends on the maternal ovaries, discharging their ova alternately, and that the father consequently has about as much or as little to do with the result as has the maker of a match with the type and violence of the explosion following its use

---

[2] THE LANCET, 1922, ii., 914.

So far as concerns the association of male and female with the right and left sides respectively, the assumption of connexion is at least as old as Hippocrates, and perhaps as old as the hills, and is a general belief in some form or another among all nations and peoples. Mankind, in all these ages, has had large experience of childbirth and its accompaniments, and the very persistence and universality of the belief would, apart from other things, tend to induce hesitation in lightly discarding it, while the inherent improbabilities of alternate action of the ovaries do not seem to be great or in any way insurmountable; but, even if these beliefs turn out to be in some or any way justified, it is very probable that they would have to be viewed in the light of a third condition which is gaining increasing weight with the progress of investigation. We refer to the sex difference in the chromosome content of the gonocyte nucleus. Many of our readers are, no doubt, aware that there is a sexual variation in chromosome number, in which certain elements, known as heterochromosomes, do not behave like the other chromosomes during maturation of the sex cell; experiments have shown that it is these elements which are intimately concerned with the production of the sexes. Such cytological observations are, of course, of a highly technical sort, and have to be proved and tested in many ways before they can pass into the charmed circle of things accepted; but the enthusiastic research devoted to the question is slowly reaping its harvest, and the number of animal forms brought within the operation of the law is increasing. Observations on the human sex cells are still in the contentious stage, and many difficulties have naturally to be surmounted, but there seems to be every reason to anticipate an ultimate solution comparable with those reached in other types. To take one of the views held, the female cell, before maturation, has two heterochromosomes in addition to the ordinary number; these are of the same type, termed X-chromosomes. At the first maturation division they do not divide in mitosis, but move apart, so that each daughter-cell has one X element in its half-nucleus. In the second division all the elements divide in mitosis, so that the mature ovum has one X-element in its nucleus. The male cell has one X- and one smaller Y-element in its immature state: these move apart in the first division so that one of the daughter-cells has an X-element and the other a Y-chromosome: in the second division these divide, whence, of the four resulting spermatids, two have one sort and two the other variety. At fertilisation, if the mature ovum conjugates with a spermatic nucleus containing an X-chromosome, the new nucleus contains two X-elements, and is therefore female: if it meets with a spermatozoon with an accessory Y-element, the resulting nucleus contains X and Y and is consequently male.

Such a view, of course, puts the chances of sex-determination to the account of the paternal contribution. This seems to be the usual arrangement among animals so far investigated, although the reverse holds in certain birds and some insects. The conditions in the human ovum and male cell are, as we have said, at present matters of controversy, but there is no doubt that these conditions will, in the future, be considered of primary importance, and will take the main place in theories about sex-determination.

THE OPIUM CONFERENCES AT GENEVA.

We have from time to time[1] endeavoured to trace the progress of measures, both national and international, calculated to control the traffic and check the abuse of drugs of addiction, such as opium, morphia, cocaine, and heroin. In this country the Dangerous Drugs Acts of 1920 and 1923 gave legislative effect to the International Opium Convention signed at The Hague in 1912, so far at any rate as internal trade was concerned. The international aspect of the question, entrusted by the Peace Treaties to the League of Nations, has entered upon a new phase by reason of two international conferences which held prolonged sessions at Geneva from November to February last. The first conference produced an agreement, a protocol, and a final act signed on behalf of France, India, Japan, Netherlands, Portugal, Siam, and Great Britain, in the case of the last three with declaratory reservations. These instruments purport to ensure the execution, and strengthen the undertakings, set out in Chapter II. of The Hague Convention of 1912 in regard to "prepared" opium or opium for smoking. That chapter pledged the contracting powers to take measures for the gradual and effective suppression of the manufacture of, and internal trade in, "prepared" opium and the prohibition of its import or export either immediately or as soon as possible. The new instrument seeks inter alia to make the business a Government monopoly, and its authors, impressed with the magnitude of smuggling, postponed the suppression of the use of "prepared" opium to a period of not more than 15 years from a time when a Commission, appointed by the League of Nations Council, shall have reported that the export of raw opium from producing countries no longer constitutes a serious obstacle to the reduction of the use of "prepared" opium in consuming countries. The American delegation urged that the suppression of the use of "prepared" opium for smoking should take effect in 10 years, or at most 15, from ratification of this agreement, and not from some indefinite future date; they were, however, over-ruled. It was this point of divergence, together with another more serious one arising at the second conference, which led to the withdrawal of the American delegation, followed by that of the Chinese.

The second conference, which began with 41 States represented, was chiefly concerned with the national and international control of the dangerous habit-forming drugs dealt with in Chapter III. of The Hague Convention. The preparations of Indian hemp are now added to those of opium, morphia, heroin, and cocaine as scheduled drugs. The second conference resulted in a convention, a protocol, and a final act. Mr. Zahle, the able chairman of this conference, in summing up the results of the labours of this the largest and most difficult conference in the history of the League of Nations, made no claim to complete success. He said that it "had not removed the world's drug evil; but that, on the contrary, it had left behind questions which will not be solved for years, possibly even decades." He nevertheless claimed that it had secured publicity for the "terrible scourge from which so many different branches of the human family are suffering," and that it had created "a real mechanism for the day to day execution of The Hague Convention." He held that "the keystone of this control is the Central Board of eight permanent and disinterested experts," to be appointed by the Council of the League of Nations, charged with the collection of statistical and other information as to the import of the scheduled drugs and their consumption as well as the invigilation of international trade therein, and armed with recommendatory powers as to limitation thereof.

Mr. Zahle frankly admitted that "if manufacture and transit have been well cared for the same success cannot be claimed for production." It was here that the American propositions, accepted in principle by the Assembly of the League, failed to secure adoption by the second conference. These propositions were: (1) "If the purpose of The Hague Opium Convention is to be achieved according to its spirit and true intent, it must be recognised that the use of opium products for other than medicinal and scientific purposes is an abuse and not legitimate"; and (2) "In order to prevent the abuse of these drugs, it is necessary to exercise the control of the production of raw opium in such a manner that there will be no surplus available for non-medicinal and non-scientific purposes." Mr. ZAHLE allowed that "no voice was raised, and indeed no voice can be raised, against the justice of the principles enunciated by the American delegation." They were, however, regarded by many of the delegates as too idealistic. They appeared to conflict with the long-established habit of opium-eating in India, officially regarded as "legitimate." Moreover, such great opium-producing countries as Turkey, Persia, and China, even if they have the will, do not appear to have the power, at the present time, to limit the profitable production of opium to the slender requirements of medicine and science. As Mr. ZAHLE observed: "The producing countries realise that in total they are providing far more drugs than the world needs." He even went so far as to say that the conference had learnt that these drugs are "sedulously sought by a small coterie of people willing to poison their fellows for profit." Thus, the Geneva conferences, unable to realise the ideal, fell back upon more or less successful endeavours to idealise the real.

Annotations.

"Ne quid nimis."

REGIONAL ANÆSTHESIA.

THE methods of local and regional anæsthesia have received in this country less notice than they deserve, and this is to be attributed rather to the perfection to which our anæsthetists have brought the methods of general anæsthesia than to any want of enterprise on the part of British surgeons. Those who have visited surgical clinics abroad must have been struck by the small attention given to the technique of general anæsthesia, and for this reason we do not wonder that surgeons in those various countries have turned more and more for assistance to methods of injection. We in this country, on the other hand, are apt to forget that an unconscious and immobile patient is by no means safe from the shock of nervous stimuli, and to ignore the wonderful protection which local methods afford. Once again we see that medicine has no national bounds and that we must all learn from each other. The introduction of non-toxic substances, of perfected equipment, and of simplified technique have now made it possible to carry out any operation painlessly without other aid than local methods, and even under general anæsthesia there are few major operations in which the use of local and regional methods are not of advantage both to the surgeon and to his patient.

Of modern methods one of the most important is paravertebral anæsthesia, to which Mr. Stanford Cade, Hunterian Professor of the Royal College of Surgeons of England, calls attention in the Hunterian lecture published in this issue of THE LANCET. It was introduced by Läwen in 1911, and extended by Kappis and Ziegel, who in 1919 had performed 2000 operations by this means. In this method each spinal nerve must be injected with novocaine as it emerges from the intervertebral foramen, until the nerve-supply to the region of operation has been completely blocked. It is applicable to any region, but it requires considerable skill and it is a little tedious. In the neck it gives an excellent anæsthesia for operations on the thyroid, but in the dorsal region it is of peculiar value. Under it the most extensive operations on the thorax can be carried out with a degree of safety and an absence of shock unequalled in any other method, and this in patients whose pulmonary condition renders them bad risks for general anæsthesia. A more recent development, splanchnic anæsthesia, is dwelt upon in our columns this week by Mr. Stanley Hillman and Dr. R. E. Apperly. This ingenious method, which we owe to Wendling and Kappis, depends on an infiltration of the semilunar ganglia and the splanchnic nerves, where they lie in loose cellular tissue on the body of the first lumbar vertebra. This region can be reached from behind with extreme facility and safety, and the whole procedure takes very little time. As a result an almost complete block of afferent impulses from the stomach is obtained, abdominal relaxation under light anæsthesia is so complete that manipulations are greatly facilitated, and the absence of shock is astonishing. Whether used by themselves or as adjuncts to general anæsthesia, there can be no doubt that these methods place a very powerful weapon in the surgeon's hands, adding enormously to the safety of his work, and in many cases enabling him to carry out radical operations with success in conditions which would otherwise be beyond his powers.

HOSPITALS AND ACCIDENTS.

LAST year, according to a Home Office return that has just been published, there were 98,215 street accidents in Great Britain; in 1923 the number was 83,101. There has thus been an increase in 12 months of more than 15,000. Of these accidents 3631 were fatal as against 2979 in the previous year, and all but an inconsiderable fraction of the deaths were caused by mechanically propelled vehicles—indeed, the motor was concerned in more than two-thirds of all the accidents. Curiously enough the pedal cycle is becoming increasingly dangerous both to the rider and the public, and in 1924 it was responsible for 241 of the fatal accidents—32 more than in the year before. The more thickly congested traffic becomes the more accidents there are likely to be, but it is beyond question that the perils not only of crowded streets but of country roads are enormously increased by reckless driving and the mania for speed. The Jehu of the motor-cycle is an especially furious driver, and he is little disposed to moderate his pace even when he has a female pillion-rider behind him, though it must be admitted that these young ladies have developed amazing skill in balancing, chiefly, perhaps, by cultivating the difficult art of sitting perfectly still. The pedal cycle is, however, a constant source of danger in busy streets. The pedestrian who sees a clear crossing is daily disconcerted by the sudden darting out of an unsuspected cyclist, who perceives a golden opportunity of saving the ten seconds or so which appear to be vital to his purposes. The consequences we see in the 18,363 street accidents in which pedal cycles were concerned last year—nearly 3000 more than in 1923. It must, moreover, be remembered that the total of nearly 100,000 accidents is made up entirely of misadventures which came under the cognisance of the police, and takes no account of the large number of minor mishaps which just missed being serious and were not reported.

The large and rapid increase in traffic accidents is in many places causing serious trouble to the hospitals, which find the beds sorely needed for the reduction of their waiting lists blocked by street casualties. A glance at the report of almost any large hospital for the past year will show how considerable is this obstruction. Thus we find that Leeds General Infirmary, which had a waiting list of 1347 on the last day of 1924, was compelled during the year to treat more than 18,000 casualty and emergency cases, 410 of which were the outcome of motoring accidents. Wolverhampton Hospital admitted 1168 accident and emergency cases, in addition to treating 9303 out-patients suffering from accidents. The East Suffolk Hospital at Ipswich reports "a great increase" in the number of street and road accidents, and this in a district mainly rural. These are instances taken at random from reports which chance to be available at the moment; they might be paralleled in scores of other cases. The Ipswich board of management suggests, as so many other people have done, the permanent reimposition of the obligation upon cyclists to carry rear lights. This is clearly desirable as a measure of general safety, but the vast majority of traffic accidents occur in daylight, and they are caused in the main by ignorant, reckless, or furious driving. Many drivers know little of the rules of the road, and many of those who do are careless and selfish. But the real danger, and the cause of the majority of accidents, is excessive speed. The precise nature of the safeguards that will presently have to be adopted is open to argument, but we cannot afford to allow accidents to increase at the rate of 15,000 a year and to put a consequent strain upon hospitals which gravely augments the congestion from which most of them are suffering.

SURGICAL TRAUMA AND SYPHILIS.

IN a paper based on the records of 78 cases in the Section on Dermatology and Syphilology of the Mayo Clinic, Dr. William H. Goeckermann[1] discusses the effect of surgical trauma in patients suffering from syphilis, with special reference to the healing of the operation wound. Of the 78 patients 50 had received some treatment for syphilis, and 28 had not been treated. Only one of the patients in the former group showed any delay in the healing of the wound. The case was one of cancer of the breast in which extensive resection was carried out. The infection was obviously pyogenic, and healing was not stimulated by antisyphilitic treatment. Three patients in the treated group died shortly after operation, but without syphilis being obviously responsible for the fatal issue. In the second group, in which antisyphilitic treatment had not been adopted for various reasons, five patients showed distinct delay in the healing of their operation wounds, but in three of them a gumma had been incised under the mistaken belief that the lesion was an abscess. The writer is of opinion that a considerable number of patients with syphilis are operated on without the surgeon being aware of the condition, and considers that the operation risk could be reduced to a minimum by a routine Wassermann test and proper treatment in certain cases.

THE HARBEN LECTURES.

THE Harben lectures for 1924 are published in the March and April issues of the *Journal of State Medicine*. In them Prof. E. L. Collis collects a mass of statistics dealing with the prevalence of tuberculosis before the war, during the war, and since the war in many countries. Sweden, Australia, Prussia, the United States, Czecho-Slovakia, the Netherlands, Denmark, and Japan all come under review. Ireland, Scotland, Wales, and England are dealt with in the second lecture. The figures will be of special interest to epidemiologists. After a careful survey of the data, Prof. Collis allows himself to draw two deductions. (1) That phthisis mortality in early adult life is an expression of resistance, lowered by malnutrition, and is particularly manifest in the female sex during puberty and the child-bearing period of life. By malnutrition he means a food-supply inadequate to the demands of activity. Thus a supply adequate for domestic life may be inadequate for industrial activity. (2) That phthisis mortality in late middle-life is an expression of resistance lowered by wear and tear and is particularly manifest in the male sex. Prof. Collis concludes with a consideration of occupational records. Amongst his other deductions he points out that the aggregation of workers in indoor occupations favours the spread of tuberculous infection, and that infection from adult to adult thus becomes a main influence in the spread of pulmonary tuberculosis. He also shows that dust which impairs the vitality of the lungs predisposes to tuberculous infection at that late period of life when wear and tear on tissues is becoming most pronounced. Silica dust, he says, exerts a peculiar influence in damaging the lung tissues and probably by its toxic action in also causing fibrosis of the kidneys. The findings of Prof. Collis are in general agreement with those of other workers and observers. It has frequently been pointed out that the male mortality from tuberculosis is almost always in excess of that of the female, and that this excess is much more pronounced in the case of inland manufacturing towns than it is in seaports where much of the work is out of doors. As regards the effect of food, it was observed during the war that women who worked in factories at which there was a good canteen enjoyed better health with the harder work and the better food than they did before the war with lighter work and an inadequate dietary. "The evidence," says Prof. Collis, "is definite that from age 10 to about age 30 the tuberculosis problem is essentially a food problem."

DR. KNOCK.[1]

EVEN as a small boy Dr. Knock was interested in medicine, and he studied the advertisements of patent medicine vendors so that at the age of 12 he was "a doctor at heart." He took a degree in ancient history and then sold shirts in Marseilles until, finding himself out of work, he applied for post as ship's surgeon, which he got after candidly admitting that he was no doctor! After six months of his "trial and error" methods he re-entered the business world and made sufficient money as a dealer in monkey-nuts to enable him to take a medical degree, receiving honourable mention for his essay entitled "The Misuse of the Word Cure in Medicine." In the first act of this play by Jules Romains, produced last year in Paris, which Mr. Harley Granville-Barker has now translated, we find Dr. Knock just arriving at a country railway station near the village of St. Maurice and being met by Dr. Parpalaid from whom he has bought, by letters and without inspection, what proves to be an almost negligible practice. In the next act we find Dr. Knock in his consulting-room, complete with wall-charts and modern apparatus, arranging with the town-crier to have a scheme of free consultations on Monday mornings cried around the village. He interviews the schoolmaster with regard to lectures on hygiene and the local chemist as to closer coöperation. "Every single soul in the place," he says, "is, ipso facto, a potential patient." Presently there arrive those who wish to take advantage of the free consultations. Some have come as a joke, the farmer's wife to have a look at the new doctor, a faded "lady" to get advice on the cheap, but they all leave the consulting-room quite convinced that they are seriously ill. The third act takes place in the hall of the local hotel, now full of patients, and Dr. Parpalaid arrives to collect the first instalment of the purchase money. He is at first astonished and then horrified at the results which Dr. Knock has obtained in the course of his first three months, and there is an amusing speech by Dr. Knock extolling the great science of medicine which ends with a rapturous description of "two hundred and fifty clinical thermometers lifted in unison and gently placed and held beneath two hundred and fifty silent tongues!" Dr. Knock's forceful manner succeeds in overcoming his predecessor's scruples and the play ends with the rather pathetic spectacle of the old man asking for advice about his own health.

The play is a clever ridicule, not of scientific medicine but of the mentality of the public, and even if Dr. Knock's methods were reprehensible—and they were though to some extent he deceived himself—he was aided and abetted by the entire village which to a man and woman welcomed his presence among them. Mr. Granville-Barker has had a difficult task in providing an English version which is not a translation, but a real adaptation for the English stage. Just here and there the crisp French epigram has given place to an English sentence which is not quite so telling, but on the whole the rendering is an exploit.

SCHOOL FEEDING.

THOSE interested in food at schools will find in *Science Progress* (April, 1925, p. 643) a readable common-sense survey of the subject by Dr. G. E. Friend, medical officer to Christ's College. Institutional dietetics labours under many disadvantages from which the domestic life is free. Fair criticism seems to be hardly possible; the recipients habitually criticise everything adversely to such a degree that the providers are driven into maintaining even the indefensible positions into which ignorance, carelessness, and monotony may have led them. It is, too, no doubt true, as Dr. Lyttelton has lately emphasised, that a certain amount of discipline in food is a most desirable part of the training in self-control which every school must of necessity undertake. Here, again, there is the perennial difference of opinion between the pupils and most of the parents on the one hand, and the schoolmaster on the other as to when fair discipline ends and tyranny begins. Dr. Friend is neither pupil nor master, and his testimony is of the more value. With an average age of about 14½, he judges that about 3000 or perhaps 3200 calories a day is the right amount, given in three meals at 8, 1, and 6, with a supper snack for the older boys. Work in school before breakfast, and even chapel, he entirely condemns, and holds that breakfast must be a substantial meal—meat, fish or porridge, with jam or marmalade, and unlimited bread and butter. Too short a time is often allowed for meals, and he points out that the smaller boys who get served last are apt to suffer most. Lack of variety and adaptability, bad and slovenly service, and poor cooking are other faults which he mentions. He urges that these defects become less apparent if the whole school of, say, 500 boys, is served from a central kitchen rather than in separate houses, because really expert superintendence can be secured. Little is said about vitamins. Dr. Friend evidently takes the sensible view that they are apt to be overdone nowadays with some neglect of calories and protein. But he is emphatic that butter must be provided, and not margarine. The known difference is that butter promotes growth and margarine does not; and this raises one of the many curious questions which have come up in the recent flood of interest in what we eat. It is generally accepted without question that it is wholly desirable that young persons should be grown to the maximum possible size, and that a boy 6 feet high is a better product than one 6 inches shorter—a reasonable build being always premised. Putting aside all but purely materialistic considerations, one wonders what justification there is for this. The youth of to-day certainly provide the most lovely spectacles of big growing boys and girls; they are a joy to look at, but are they going really to be healthier or more effective citizens than their meagre grandparents? They will certainly be more expensive, for they have more to keep up. There is a clinical impression that largely built people stand illness badly; the late influenza was repeatedly reported to be particularly fatal to the hearty and robust, and it is possible that the American insurance companies may find out later on that over-size is as disadvantageous as over-weight. Life often seems to last extra long in tiny bodies. But even if small people are healthier, the prestige of size may still encourage the young to grow as much as they can. Small people are often rather touchy on the subject of stature; so much so that it might be inadvisable to give the stature of some of our greatest people, lest that should be the one of their qualities which they least desire to be broadcasted.

THE BRITISH SOCIAL HYGIENE COUNCIL.

THE National Council for Combating Venereal Diseases (Incorporated), of 102, Dean-street, Oxford-street, London, W., will henceforth be known as the British Social Hygiene Council. The resolution to effect this change of name was passed at an extraordinary general meeting of the Council held on April 6th, and it will be submitted for confirmation at a second meeting of the Council to be held on May 4th. The arguments in favour of this change, as set forth by the Council, are interesting in that they show the progress which has been made in embracing the widest aspects of the venereal diseases problem. The Council consider that the need that originally existed for emphasising the fact that venereal disease was a public health problem is not so acute after the last ten years of propaganda on the subject. The work of the Council during the last two years has extended considerably along preventive lines. This brings the representatives of the Council into touch with many social and educational bodies that are anxious and willing to consider problems relating to the development of self-control and a higher standard of sex conduct among the rising generation. The attainment of a higher standard of sex conduct is essential for the complete elimination of venereal disease, but it is by no means necessary, nor in fact desirable, the Council holds, to give such educational lectures under the title of venereal disease, as the field covered is so much wider, and for this purpose many groups can be reached under the title Social Hygiene that would not be accessible under the old title. The Board of Trade and the Ministry of Health have both notified their approval of the proposed change to British Social Hygiene Council. In order not to break all links with the past, the Council suggests that the words "lately National Council for Combating Venereal Diseases" may be inserted under the new title on certain publications. Thus we may announce the Second Imperial Social Hygiene Conference, which is to be held in October at the British Empire Exhibition, Wembley, as organised by the National Council for Combating Venereal Diseases. This conference is the outcome of requests received from overseas, and the whole of three days, from Oct. 5th to 7th, will be given to a discussion of Imperial problems.

THE LETTERS OF GUY PATIN.

Dr. F. R. Packard has reprinted[1] with sundry additions the very interesting articles which appeared in "Annals of Medical History," Vol. IV., Nos. 2, 3, and 4. The book is chiefly made up of extracts from Guy Patin's letters to his various correspondents which give a life-like picture of medical affairs in Paris during the seventeenth century, and it opens with a useful historical résumé of the period, an understanding of which is necessary for the right appreciation of Patin's letters. These letters, which were not written for publication, contain the most amusing and often singularly caustic reflections upon his brother physicians, whether individuals or corporations such as the Apothecaries, and also upon statesmen even in the highest places, such as Richelieu or Mazarin. After the fashion of Vergil, who desired his executors to burn the MS. of the Æneid, Patin asked his chief correspondent Spon to burn his letters, but luckily for literature neither request was granted. Among the private and family matters contained in the letters Dr. Packard quotes one letter which is particularly delightful, giving an account of the death of Patin's mother-in-law. Writing to Spon, he says: "Do not weep much for the death of my mother-in-law, she was not worth it. She was a *good* woman, rich and avaricious, who feared nothing so much as death, which nevertheless seized her quite suddenly at the end at her beautiful country house at Cormeilles." Dr. Packard is to be congratulated upon having provided English readers with specimens of the wit and satire to be found in Patin's correspondence, and we hope that it will lead many to read the originals.

CHEMICAL WARFARE: LEWISITE.

IT is perhaps too much to expect that chemical warfare is a matter merely of historic interest, though most of the medical profession will continue to hope that the Washington Conference was but a beginning of a series of international debates which will in time bring about a material limitation of armaments and of the more barbarous aspects of war. Such a wish is enhanced by the study of recently published books, which put before us the main known facts concerning the poisonous substances which have been used, or which are available, in warfare. Of such chemical substances the one which at present appears the most potentially dangerous is an American invention popularly known as Lewisite. Much has been rumoured concerning this compound, and headlines in the lay press have appeared from time to time of so dramatic a nature that it appears worth while to repeat some of the more scientific data available to us. These are to be found in a volume[1] recently published by Lieut.-Colonel Edward B. Vedder, of the Medical Service of the United States army, who has collated in an interesting book all the facts concerning chemical warfare which are likely to be of use to medical officers. Lewisite, or β-chlorvinyldichlorarsine, is a heavy, oily liquid prepared by passing acetylene through arsenic trichloride in the presence of aluminium chloride. It is readily hydrolysed by water, especially in the presence of alkalis. Although its effects in actual warfare have never been tested it appears to be a weapon of even greater efficacy than was dichlordiethylsulphide ("mustard gas"). The exposure of dogs to the vapours of this substance rapidly leads to intense irritation of the eyes, nose, throat, and upper alimentary and respiratory tracts. A membranous exudate makes breathing difficult and painful, and if death is not produced within two days it usually ensues a few days afterwards from the purulent bronchitis and broncho-pneumonia which follow the initial respiratory lesions.

These effects of lewisite are not materially different from those of mustard gas, where the exposure leads to fatal issue, but it is in its effects on the skin that it appears likely to prove far more deadly if ever put into use in warfare. The irritation and burning of lewisite appear very quickly after the application of the liquid substance to the skin, and even in comparatively minute doses sufficient of it is absorbed to produce rapid death from arsenical poisoning. The lesions thus produced affect chiefly the tissues immediately underlying the seat of burning, but the lungs and kidneys show toxic effects in all cases, and arsenic can be recovered from practically every tissue of the body. When death is not produced the burns themselves tend to be of a most serious nature; extensive necrosis of the skin, subcutaneous tissues, and underlying muscles occurs, leaving infected areas which can only heal slowly by granulation. The treatment of such injuries is believed to be effected most satisfactorily by the application of weak alkalis, such as 5 per cent. sodium hydroxide or a ferric hydrate paste.

In view of the potential horrors of such weapons the defence of the "humanity" of chemical warfare made by Colonel Vedder in his introduction seems a little superfluous; but Mr. J. B. S. Haldane,[2] who attempts a reasoned defence of chemical warfare in general on the grounds of the comparative harmlessness of gas warfare, uses dialectical adroitness almost excessively. None the less, "Callinicus" is an arrangement of facts whose seriousness should not be impaired in the reader's estimate by the exploiting of humorous gifts.

INDUSTRIAL HYGIENE IN MOSCOW.

IN the February issue of the *Journal of Industrial Hygiene*, which has only just reached us, an objective account is given by A. Hamilton and R. Hilles of the hygiene of factories and workshops in Moscow. Industrial medicine, it appears, has become a required branch in the Russian medical curriculum, and visits to factories are part of the prescribed work. Moscow contains a wonderful Museum of Safety housed in the former palace of the Galitzin family, one room of which is given over to anti-alcohol propaganda; normally, distilled liquors are forbidden in the country. Efforts are made at institutes to fit the work to the man and the man to his work; all sorts of physiological and psychological experiments are carried out; but in the factories themselves little evidence exists yet of efforts to prevent unnecessary fatigue or to increase efficiency. The factories present extremes far wider than exist in America and Western Europe; almost alongside one another the best and worst possible conditions of work are to be found. "The theory of Soviet Russia," the authors write, "is that labour, industrial and agricultural, is the foundation of the State and that the life of the industrial worker should centre round the factory just as the life of the peasant centres round the farm. Their ideal is to have in connexion with each factory not only communal houses but also a creche, a kindergarten, a hospital, an amusement centre, and whatever else the workers need and want." Wages for men and women are the same for the same work, but the women seldom carry out the same work as the men. It is encouraging to learn that industrial medicine is engaging the service of some of the ablest men and women in Russia.

BROKEN GLASS AS A POISON.

A YEAR ago we commented[1] on correspondence in *Municipal Engineering* on the subject of powdered or broken glass as a "poison," and since that date a number of provincial newspapers have stressed the seriousness of particles of glass in bottled foods, chiefly jam. In one case reported a public analyst found that 8 out of 11 samples of jam in glass containers showed the presence of particles of glass, and another analyst found 8 samples out of 49 to be similarly contaminated. According to these reports the Ministry of Health was making inquiries into the matter. We certainly endorse the prevalent opinion that the matter is a serious one—powdered or broken glass may cause serious symptoms and on occasion even death—and that every measure should be taken to prevent the occurrence of glass in food. This state of affairs could no doubt be greatly diminished by the rejection of badly made containers and by destroying the food which when poured hot into glass containers causes the container to fly, instead of returning it after straining to be reboiled and subsequently poured into fresh containers—a practice common, we understand, among makers of cheaper brands of jam. Ideally better than such destruction would be the use of metal containers which possess additional advantages when sterilisation and keeping qualities are also considered, although it occasionally happens that successful prosecutions are undertaken for the presence of tin in the food issued in tinned iron containers. But the public are conservative and would be likely to resent an innovation such as jam in tins. So much is this the case that bottled fruit imported in tins may be transferred to bottles before sale. Nevertheless, whilst admitting fully the potential dangers, we emphatically dissociate ourselves from any suggestion that broken or powdered glass is a common cause of appendicitis or a cause at all of cancer. Those who are rightly ventilating this subject in the press are doing their cause harm by suggestions such as these which entirely lack foundation.

MENTAL HOSPITAL ADMINISTRATION.

DURING the week two important conferences have been held, convened by the Chairman of the Board of Control, to consider some aspects of mental hospital administration. For the Tuesday conference invitations were sent to the various bodies interested in the training and registration of nurses, with a view to obtaining some light upon the best solution of the nursing problem in mental hospitals. The Departmental Committee which reported in November last made certain recommendations in the direction of so increasing the status and emoluments of trained mental nurses as to make the career attractive to a greater number of educated women. The Committee recommended the grading of mental hospitals according to training facilities and the extension of the practice of seconding mental nurses to general hospitals, as well as the appointment upon the inspectorate of the Board of Control of a doubly-trained nurse to advise the various medical and nursing officials. The Tuesday conference dealt seriatim with the principal points raised by the Departmental Committee, the subject in each case being introduced by the medical superintendent of an important mental hospital. Finally, the matron of the Cardiff City Mental Hospital spoke of the nursing of male patients by women nurses, on which subject (by a useful coincidence) Prof. G. M. Robertson gave to the Royal Commission last Saturday the fruits of his pioneer work. Experience at Morningside has convinced all who have worked there of the therapeutic value of the female nurse in the acute male wards, where women appear to have more power than men in subduing excitement and their presence tends to reduce any tendency to roughness.

The second conference on Wednesday was asked to consider the provision of further mental hospital accommodation, and to it were invited the medical superintendents of county and borough mental hospitals, as well as one or more representatives of each visiting committee. Sir Frederick Willis in his letter of invitation remarked that the vacant accommodation in mental hospitals in this country is at the moment sufficient to last only for another year or so, adding that this is not due to increase of the incidence of insanity but simply to the natural growth of population. He went on in his letter to suggest various ways in which accommodation might be set free in existing institutions: by transfer of certain patients to Poor-law institutions, by making a wider use of absence on trial and boarding-out, by discharging others to the care of relatives, and by boarding outside the hospital itself nurses in excess of those required for the proper conduct of the institution. Many patients now in mental hospitals would be better in institutions for mental defectives were beds available for them. Nevertheless, the question of providing new accommodation could not be avoided, and it was round the supply of additional beds that discussion centred.

The annual Congress of the Royal Institute of Public Health will be held in Brighton and Hove from Wednesday, May 27th, to Monday, June 1st inclusive, Lord Leconfield, Lord Lieutenant of the county of Sussex, presiding. Discussions will be held and papers read on important subjects in each of the six sections of the Congress—namely: (1) State Medicine and Municipal Hygiene; (2) Naval, Military, and Air; (3) Industrial Hygiene; (4) Tropical Diseases; (5) Pathology, Bacteriology, and Biochemistry; and (6) Women and the Public Health. Copies of the programme and full particulars may be obtained from the Secretary of the Institute, 37, Russell-square, London, W.C. 1.

WE regret to announce that Sir John MacAlister, the Secretary of the Royal Society of Medicine, has had to resign his post on account of ill-health; a new secretary will be appointed as soon as possible.

THE death is recorded, at the age of 70, of Surgeon Vice-Admiral Sir Arthur William May, K.C.B., which occurred on Monday, April 20th, at St. Tudy, Cornwall. Sir Arthur May was Director-General of the Medical Department of the Admiralty from 1914 to 1917.

THE next social evening of the Royal Society of Medicine will be held on Monday, May 4th, at 8.30 P.M., when Fellows and guests will be received by Sir StClair Thomson, the President. At 9.30 P.M. Dr. Robert Hutchison will give a short address on Dr. Samuel Johnson and Medicine, illustrated with eighteenth-century portraits.

THE memorandum of evidence prepared by the British Medical Association has been placed before the Royal Commission on National Health Insurance, and the witnesses-in-chief are to appear before the Commission on April 30th and May 7th. These witnesses are Dr. R. A. Bolam, Chairman of Council; Dr. H. B. Brackenbury, Chairman of the Representative Body; Dr. H. G. Dain, Chairman of the Insurance Acts Committee; and Dr. Alfred Cox, Medical Secretary.

SOUTH LONDON HOSPITAL FOR WOMEN.—The annual general meeting of the hospital will be held at Gresham College, London, E.C., on Wednesday, April 29th, at 3 P.M. The Hon. Mrs. E. L. Franklin will be in the chair, and Lord Riddell, Dr. Louisa Martindale, and Mr. G. Murray Hill will speak.

INVALID CHILDREN'S AID ASSOCIATION.—By permission of Sir John and Lady Ward the annual meeting of the Invalid Children's Aid Association will be held at Dudley House, Park-lane, W. 1, on Tuesday, May 12th, at 3 P.M. Lady Titchfield will preside, and the Right Hon. J. Ramsay MacDonald, M.P., Sir Bruce Bruce-Porter, Dr. Letitia Fairfield, Miss Madge Titheradge, and the Rev. J. C. Pringle will be among the speakers. Tickets are necessary for admission, and can be obtained from the Secretary, 217, Piccadilly, London, W. 1.

ILLEGAL PRACTICE BY A DRUGGIST.—In a case recently heard in the Nuneaton County Court before Judge Staveley Hill, the Society of Apothecaries were plaintiffs, and Mrs. Ashton, of the Coton Drug Stores, Nuneaton, was the defendant (THE LANCET, March 21st, p. 627). The action was brought under the Apothecaries Act, 1815, to recover a penalty of £20 from the defendant for having acted as an apothecary without qualification. From the evidence, it appeared that in September last there was an outbreak of small-pox at Nuneaton. Early in November a Mrs. Hutchinson found one of her children with a rash. She took the child to the defendant's shop and asked the defendant if the child had small-pox. After looking at the rash the defendant said "No," but she thought it was a chill on the blood. The defendant supplied a bottle of medicine for which she was paid 1*s.* Towards the end of November the medical officer of health received notification that a sister of the child in question was suffering from small-pox, and on visiting the house he found four members of the family suffering from the disease. The child seen by the defendant had an old rash and the medical officer was of opinion that this child had had small-pox for three weeks. He ascertained that during this time the child had been attending school and in consequence he vaccinated all the school-children. It was contended that as the result of the failure of the defendant to diagnose the disease correctly other children had been infected. The judge said that, having carefully considered the authorities, he was of opinion that the defendant had brought herself within the statute, and gave judgment in favour of the plaintiffs for the penalty and costs. An appeal against this decision was entered by the defendant but afterwards abandoned.

Modern Technique in Treatment.

A Series of Special Articles contributed by invitation on the Treatment of Medical and Surgical Conditions.

CXIX.—THE TREATMENT OF FROST-BITE.

Frost-bite is a local condition due to the action of cold upon the tissues of the body, as a result of which an area more or less limited in extent is deprived of its blood-supply. The condition is produced in two very different ways. In the first the direct action of cold upon the skin and underlying structures causes constriction of the capillaries and small blood-vessels, whereby they are so narrowed that no blood can pass through them ; in the second a reactive process, there is exudation through the damaged vessel walls into the surrounding tissues of the frost-bitten part, as a result of which the vessels again become constricted, and circulation cut off.

The first condition shows as an ischæmic waxy-white patch, well defined in outline, somewhat resembling the rapidly produced evanescent white area which results when ethyl chloride is used for local anæsthesia. The naturally produced condition has a somewhat dirtier, waxier appearance, with none of the "rime" characteristic of ethyl chloride. The second condition resembles the ordinary chilblain : it is aggravated by long-continued ischæmia, and by too rapid a return flow of blood. Certain factors predispose. They are those which cause a lowered vitality and a depressed circulation. The most important are : Cold (of the body generally), fatigue, exhaustion, hunger, and vitamin deficiency, especially scurvy. All these not only render the parts more liable to frost-bite, but by their mental effect cause the man to be less vigilant of its onset, a most important factor. Causes acting locally are winds, moisture, and grease. The parts of the body most liable to attack are the extremities, the exposed parts of the face, especially where the skin is stretched across underlying bone—e.g., the sides of the nose the cheek-bones, and the chin ; the ears, especially the tips and edges ; the fingers and hands ; the feet, especially the toes and heels. The parts most liable to permanent damage are the feet.

The frost-bitten part, if treated early and on proper lines, recovers completely ; if neglected the part dies and gangrene sets in. When the damage is superficial the skin becomes dry and black, and finally peels off, leaving a clean new skin underneath. In the case of extremities such as the toes, the damage may involve the whole thickness, so that they become dry, black, and shrivelled, producing the typical clinical picture of dry gangrene. The condition due to exudation is more serious. The part is at first dusky red, with a varying amount of swelling and œdema, and very irritable. Frequently blisters form which may contain straw-coloured serum, or in worse cases a thick purplish exudate. The part readily becomes septic, and moist gangrene follows, with absorption of toxins and severe effects upon the general health.

Signs and Symptoms.

The onset of frost-bite is often insidious, and on inspection of the part in a suspected case there may be little to see. The waxy appearance may not be present, since the primary frost-bite may have passed off, or the condition have been produced by the prolonged action of less severe cold, especially if associated with wet.

Explorers are taught to regard all doubtful cases with the greatest suspicion, and to look upon the following signs as indicating that a part is seriously damaged : (1) Cessation of circulation, as evidenced by the lack of response to finger pressure ; (2) loss of heat—the affected part feels colder than the surrounding areas ; (3) loss of sensation ; (4) inability to use the part—e.g., if the toes are frost-bitten they cannot be freely moved (this does not prevent walking, for there are numerous instances where men, to save their lives, have hobbled along on frost-bitten feet, with disastrous results locally) ; (5) changes in colour, especially any suggestion of mottling, which is at first red and pink, dark red and pale pink, later becoming blue-grey, and in the worst cases purple and dirty white. It must be emphasised that these signs are often very difficult to recognise, the circumstances under which frost-bite is seen in its early stages usually being very disadvantageous.

Prevention and Early Treatment.

The importance of prevention and early treatment hardly needs emphasising, but one cannot too energetically condemn the principle, still taught, of rubbing the part with snow and snow-water. To do this to a perfectly healthy piece of skin is a joke often played upon the tenderfoot, but is never adopted in polar regions for the treatment of frost-bite. The snow has often a gritty feel, not at all like the mushy stuff of this country. In the case of the tender parts, such as the face, it may actually do harm by removing the cuticle and damaged parts of the epidermis, leaving a weeping sore which heals with difficulty, and renders the part liable to further attack. It has the good point that it emphasises the danger of too great heat, which increases the amount of exudation and local damage.

Prevention is aimed at in two ways : generally by maintaining health and a vigorous circulation, and by attempting to eliminate the predisposing factors, and locally by providing suitable clothing. Whatever form the clothing takes the principle is the same—i.e., the placing of a non-conducting air-space between the skin and the cold outer air, and preventing its dislodgment. The two chief forms of clothing used for this purpose are "furs" and "woollens," which enmesh the air in the hairs and stitches respectively. The factors which tend to dislodge it are winds which blow it away, and damp or grease which takes its place. If furs are used the skin part acts as a wind-proof, but woollens must be fitted with an outer wind-proof covering. Local prevention may therefore be summarised as follows : (1) provision of suitable clothing and keeping it in repair ; (2) keeping it dry ; and (3) avoiding grease.

Clothing must be loose-fitting, with no constricting bands. With regard to keeping the clothing dry, the moisture may be derived from external wet, or internally from perspiration. Practically speaking, no part offers any difficulty except the foot-gear. Waterproof foot-gear retains perspiration, that which permits of ventilation allows access of damp from outside, and it is impossible to ensure absolute dryness. As long as the feet are warm from exercise no harm results from the damp ; it is during halts on the march and in standing-about jobs that danger arises. Damp socks should always be removed before getting into the sleeping bag and another pair substituted, or none at all worn, and the feet should receive a brisk dry rub. The moisture acts detrimentally by producing a sodden, unhealthy condition of the skin, and by acting as a much readier conductor of cold.

It is commonly believed that fats, oils, and grease are good non-conductors, and if placed on the clothes or skin help to keep the part warm. This is not true of the oils and fats met with in polar regions, for they are much readier conductors than the air which they replace. It is probable that the same holds true for all the fixed oils and fats, which are not readily absorbed by the skin. The volatile oils may be beneficial, for they are absorbed by the skin and produce dilatation of the blood-vessels with increased flow of blood to the part, but if used in such excess as to fill the air-spaces they are detrimental. Vaseline and glycerine have been used on the face to protect it from strong winds, and apparently with success, but in still air they have no value. Where it has been necessary to immerse the feet for long periods in cold water, as, for example, in the trenches during the late war, whale oil well rubbed into the skin was found beneficial in preventing trench-foot, but this condition must not be confused with frost-bite, though the end-results may be similar. A man's own hair provides excellent protection, but a beard is of doubtful value, since the moisture from the breath freezes on it, forming large masses of ice. Modern explorers keep the hair well clipped with a barber's fine clippers.

The *early treatment* of primary frost-bite consists in gently coaxing back the circulation by the application of dry gentle warmth, and the simplest and safest source of this is body heat. The application varies a little according to the part affected.

Face and Ears.—The onset occurs most frequently in windy weather. The part which has been cold becomes more comfortable, but with a feeling of numbness. Very often the man attacked knows nothing of his condition till warned by a companion, since the parts are invisible to himself. It should be a recognised custom for men in company to scrutinise each others' faces frequently, those travelling alone should keep a small mirror in the pocket. A hand warm from the mitt should be applied to the frost-bite. When one hand becomes cold the other may be used, and a companion may also "lend a hand." Very light massage may be used, but no rubbing violent enough to cause an abraded surface.

The *fingers* are commonly frost-bitten owing to the fact that fine manipulations cannot be carried out with mitts, so that the fingers have constantly to be exposed. It is easy to slip off the mitts for examination, consequently the white patches are usually instantly recognised. Treatment consists in placing the affected hand inside the clothing next the skin; commonly it is thrust under the upper part of the trousers and compressed between the thighs to slow up the return flow of blood, which is often painful. Work aloft at sea causes many cases, and is particularly dangerous, owing to the difficulty of keeping a firm grip on stays and rigging. Anything which produces pressure and tends to express blood locally predisposes, and contact with cold metal is particularly liable to produce the condition. The danger is greater if the mitts are damp and exposed to strong winds.

Feet.—In spite of close vigilance frost-bite of the feet is often not detected until long after its onset. This is due to the fact that the harder skin of the heels and the balls of the feet is relatively insensitive, and that foot-gear is comparatively difficult to remove for inspection of the suspected area. It is particularly dangerous for the following reasons: (1) the difficulty of recognition as above; (2) the feet are essentially extremities; (3) in snow it is almost impossible to keep the feet dry either from external damp or from perspiration; (4) pressure and constriction are more liable to occur than in other parts. As regards *prevention*, the question as to type of foot-gear and its care is one of the greatest problems in polar exploration. Treatment, as elsewhere, is by the application of dry gentle warmth, but the harder skin of the feet permits of more vigorous massage, which is best carried out by a companion. If after some minutes there is no sensation of returning circulation, evidenced by a feeling of intense "pins and needles," the foot should be taken inside the clothing next the skin. This treatment should be persisted in for some hours before hope of recovery is given up. For the companion who has undertaken the thawing-out process it is decidedly unpleasant; others may take turns with advantage.

If recovery is delayed for some hours the part must be kept under careful observation lest the recovery be only temporary. If there is any doubt the part must be kept warm and dry, not used, and if circumstances permit, wrapped in dry cotton-wool and lightly bandaged or placed in a frost-bite sock. Ointments and greasy preparations should not be used, and any greasiness of the feet should be removed by turpentine or methylated spirit. Heat, especially damp heat in the form of fomentations, is not to be used, for there will be an excessive reaction with exudation, formation of blisters, sloughing, possibly sepsis, and subsequent moist gangrene. In spite of all care blisters may form containing clear serum or dark-coloured viscous fluid. If the skin of the blisters can be kept intact without great discomfort they should not be opened till this can be done aseptically. Dry dressings should be applied. The best and simplest in difficult circumstances is a piece of plain white lint, cut to shape, dried at a fire, over the flame of a Primus stove, spirit lamp, or at any flame which can be produced, and scorched to render it sterile. This should be covered with similarly dried cotton-wool, and the whole lightly bandaged. No matter what the subsequent course, nothing but dry dressings should be used in the field. The treatment of a gangrenous part comes within the domain of general surgery, and has no place in this article, but I would urge all field medical officers faced with the care of this really serious condition to pin their faith to dry gentle warmth, even over long periods of time, with no other application than perhaps occasional use of turpentine or methylated spirit.

Frost-bite of other parts of the body than those described are rare. I have seen one case only: frost-bite of the penis, which occurred under the most exceptional circumstances whilst a man, utterly fatigued, was attempting defæcation in the open. Even in the lowest temperatures momentary exposure of the bare skin does not produce immediate frost-bite, but the length of time that it can be exposed with safety depends upon factors such as degrees of temperature, presence or absence of damp, and strength of wind. Much depends also on the circulation: if the body has been at rest and the circulation is sluggish, frost-bite is more easily induced than if the blood is pulsating actively as the result of hard work, walking, or running. It is the common experience of explorers that a part once frost-bitten is rendered more liable to further attack. When the body generally is cold, old frost-bitten areas can be picked out by a curious feeling of numbness, a condition which persists through life and is noticed even in our own temperate climate.

A. H. MACKLIN, O.B.E., *M.C.*, M.D. Manch.,
Surgeon to the Imperial Trans-Antarctic and the Shackleton-Rowett Expeditions.

THE BATEMAN APPEAL.

As already explained in THE LANCET, it has been felt that material assistance ought to be offered to Dr. Bateman to meet the legal expenses of his recent successful appeal against conviction and to make good the deficiency in his professional income. Accordingly, the Bateman Fund has been opened and lists of contributions have appeared in recent issues. We have received additional contributions as follows:—

	£	s.	d.
Already received and acknowledged ..	431	8	6
Dr. A. H. Burgess	3	3	0
Dr. F. A. Bearn	1	1	0
Anonymously	0	10	6
Dr. S. V. Pearson	0	10	6

Remittances should be forwarded to the Manager of THE LANCET, 423, Strand, W.C. 2, and made payable to the "Bateman Fund Account."

WOMEN'S HOSPITAL WORK.—A return compiled by the Medical Women's Federation shows that there are 321 hospitals where medical women are serving or are eligible in a professional capacity. In 308 hospitals women are either on the board of management, the house committee, or both. Three out of the 19 women's and children's hospitals in London are officered entirely by women—the Elizabeth Garrett Anderson, the South London Hospital for Women, and the Clapham Maternity; the New Sussex Hospital for Women is in the same position. In 26 similar provincial hospitals women are eligible on the staff. Practically the whole of the hospitals for women and children in London and the provinces now have women on their boards or committees.

ROYAL COMMISSION ON LUNACY AND MENTAL DISORDER.

FURTHER SITTINGS.

(Continued from p. 623.)

THE sittings of the Commission were resumed on Friday, April 17th, Mr. H. P. Macmillan, K.C., the Chairman, presiding.

Scottish Lunacy Administration.

Sir Arthur Rose, honorary chairman of the General Board of Control for Scotland, and Dr. Hamilton Marr, a full-time Commissioner of the Board, attended to give evidence. The Chairman said the scope of the Commission's reference did not extend to Scotland, but the evidence to be now given was desired for the purpose of comparison and instruction. Sir Arthur Rose said the Board consisted of five members, including two full-time paid medical officers. From motives of economy, however, the Board was not at full strength. Scotland was divided into 27 lunacy districts, not necessarily coterminous with the counties. Not every district had an asylum; a district might send its mental patients to other asylums. There were 21 asylums in the country. If a district board did not include women, two women could be coöpted. As there was no Consolidating Act, lunacy in Scotland had to be administered under a series of statutes dating from 1857.

Functions of the Scottish Board of Control.

Sir Arthur Rose said there must be two statutory meetings of the Board each year, and the Board met as frequently as business needed. Meetings of local boards were held whenever an investigation was required. Each individual patient was seen twice a year. Dr. Marr said the patients were visited in their ordinary circumstances and surroundings. Whenever an interview was requested by a patient it was always granted. It was continually present to the minds of the members of the Board that they stood, in relation to the patient, in the position of *in loco parentis*. Usually the interview was asked in order to air some delusion, but sometimes a real grievance was ventilated, such as the objection of a middle-aged female patient to bathing in the presence of young women patients. This was subsequently remedied by providing screens. In the very few cases in which there seemed to have been abuse or assault by attendants, the medical superintendent of the institution was recommended to report the case to the Procurator-Fiscal, and if that official took it up the case was tried in open court. There had been only two such cases in the last five years.

On Jan. 1st, 1924, there were in Scotland 18,266 registered lunatics (9112 male and 9154 female); 2887 were private patients. There were seven royal or chartered asylums in the country, institutions in which patients must be received if ordered to go there. In four of the seven no pauper patients were admitted. At the beginning of 1924 these seven institutions contained 3595 patients. Many of the asylums of the district boards received private as well as rate-aided patients. In Scotland only one private asylum received patients for payment at a profit. This contained 54 patients. In the 14 lunatic wards of poor-houses there were 883 patients; 1863 mental patients were living with families in private dwellings, such as farm-houses. Dr. Marr said the feeling of the Board was against the idea of a profit being made out of the care of the insane. Answering Sir David Drummond, he said a number of the private patients undergoing treatment in Scotland came from England and Ireland, and there was ample accommodation for them. Sir Arthur Rose said he believed a contributory reason was the high state of efficiency at which the Scottish mental hospitals had arrived.

Observation wards for patients with incipient forms of mental disease were instituted by the Glasgow Parish Council in 1890. They were spacious and handsome. The duration of residence was at first limited to six weeks, except in special cases, for which an extension could be granted. It was arranged that the medical commissioners of the Board of Lunacy should inspect these wards at regular intervals and report upon them. In 1923 the duration of residence was extended to six months, and additional wards were added at the general hospital at Stobhill.

Procedure.

In Scotland the procedure was the same for pauper as for private patients; there must be two medical certificates, accompanied by particulars of the case. Dr. Marr thought certificates granted after consultation was preferable to two arrived at independently, and the risk of collusion was practically negligible. One of the certificates could be given by the medical officer of the institution.

The Chairman raised again with these witnesses the question of the adequacy of the provision for patients communicating with the outside world. Dr. Marr said the sheriff could inspect asylums at any time, so could three justices of the peace and representatives of the Poor-law authority; and, generally speaking, the opportunities for communicating with the outside world were adequate. General shops for sweets and refreshments had been provided for the convenience of visitors to patients, and at Edinburgh District Asylum facilities for reading and for writing letters were provided. If a visit was refused the fact must be recorded in a book, but Sir Arthur Rose said there was no such record. With regard to discharge, the medical superintendent of an asylum recommended patients for discharge when he considered they were fit for it; he could, indeed, himself discharge a patient. In the case of admission of patients to the licensed wards of poor-houses, these were received without any order from the sheriff, and one certificate sufficed.

Boarding-out.

A matter which was fully discussed was the boarding-out system as practised in Scotland. Mental patients who, however, did not longer need material medical attention, and to whom a country life gave the best conditions, were placed in suitable homes, such as farms and small holdings. This was not quite so popular now in Scotland as a few years ago, probably, in part, because the farms and gardens in connexion with asylums were now much better managed and cultivated. These patients felt much more freedom under these conditions, and they received on the average about 12*s*. a week. It was one of the stipulations that these patients should share the whole of the home life. There seemed little risk of such patients being exploited, such as by being overworked or underfed, or both, without the Board becoming aware of it. One to four such persons could be received into one house. It was an economic system, both directly and in the capital cost of asylums.

The Chairman asked whether incipient cases could be treated in Scotland without certification—i.e., for six months on the special certificate of a doctor. The reply was in the affirmative, and that it was an excellent provision. Sir Arthur Rose said the scheme had his distinct approval, especially as it enabled patients to be seen in the incipient stage of their illness. He contemplated more treatment of mental conditions on the same lines as physical diseases were treated in ordinary nursing homes.

Morningside Asylum.

On Saturday, the 18th, the sittings were resumed, when the witness was Prof. George M. Robertson, superintendent of Morningside Asylum, Edinburgh, and professor of psychiatry at Edinburgh University.

He said the Royal Asylum at Morningside was founded by Royal Charter and endowed by philanthropic persons, and was opened in 1813. It was not carried on for gain. It was bound to receive cases from the districts it supplied, and so answered to the statutory requirements of a public asylum. The last return gave 804 patients as resident in this institution, 143 of them being rate-aided. The tariff for private patients varied from £58 to nearly £2000 a year. The treatment was on the same basis for all, the difference was in the accommodation and the attendant staff. In Craig House there were no rate-aided patients. For 46 years the institution had been closely associated with the University, which was a great all-round advantage. To the students of medicine in the University he gave every year 30 lectures—i.e., ten more than were expected—and every student was compelled to attend them. This ensured that no graduate in medicine left the University without possessing a knowledge of the principles of psychiatry; the subject was too vast to expect more. He believed students in Edinburgh received more tuition in this subject than did those at any other institution in the world. He felt so keenly that the medical curriculum was now very heavy that he had not urged that psychology should be made a subject for the final, but he would do so if the attendance and attention at the lectures fell off. For those desiring to specialise there was the searching diploma in psychological medicine, and a certain number of students had taken that.

In answer to the Chairman, Prof. Robertson said there was no provision for the sheriff in Scotland seeing the patient, and he saw no object in it, as the sheriff was not competent by examination to say whether a person was sane or insane. It was, however, valuable to have the legal scrutiny of that gentleman with regard to the certificates tendered. There had been orders signed by sheriffs when the facts, from the medical point of view, were insufficient to warrant detention, yet the sheriff in question refused to withdraw the order. Perhaps six or seven certificates in a year were sent back because they were incomplete in some detail. Answering a question by Lord Russell, Prof. Robertson said the public were entirely dependent in these matters on the honour and honesty of the medical profession. He agreed, however, that if a case went before a third person the truth was more likely to come out.

Sir David Drummond asked whether the witness considered that the second certifying doctor should be an expert in mental diseases, and Prof. Robertson replied that this would obviate many patients entering an asylum at all.

The Chairman said that in Scotland the order made by the sheriff was of three years' duration, and the witness agreed, except in the cases under the last Act which were transferred to private care. The order could be kept going by periodic renewal. The Chairman pointed out that this order did not state that the patient was of unsound mind, but only that he was a person likely to benefit from continued residence in the asylum.

Voluntary Patients.

Prof. Robertson said that from 90 per cent. to 95 per cent. of the patients entering Morningside Asylum did so without any judicial order at all, but a number came in on the emergency certificate of a single medical man for three days' detention. At the end of that time there must be confirmation by a sheriff's order. Patients and relatives "jibbed" at the idea of going before the sheriff, who was associated in the mind of the people with summonses and prosecutions. He would like certification to be done away with altogether, though admittedly there would have to be some substitute for it. He would prefer for insanity to be dealt with as a notifiable disease. The authorities would then have some responsibility in regard to each case. Instead of the present judicial procedure, these patients should be medically treated and the fact notified to the authorities. Everyone seemed desirous of avoiding formalities, and that might be taken as an indication that the formalities were wrong. In answer to the Chairman, the witness said the majority of voluntary patients appreciated that they were being treated as such, while others were indifferent about that so long as they were kindly treated. 40 per cent. of all the private patients entering the voluntary hospitals of Scotland did so as voluntary patients, and the system had the support of the public opinion of the country. Indeed, in that country there was general satisfaction with the lunacy law and its administration. The Chairman said he had never been consulted about a case of alleged illegal detention in Scotland. The system of keeping patients in private houses for six months on one medical certificate had worked well. Most of the cases recovered within six months. If a patient did not recover in that time, it was necessary to get sanction from the Board of Control to continue the treatment of such patient indefinitely.

Female Nurses in Male Wards.

Prof. Robertson said his policy had been to have matrons at the head with full authority over all the nurses of both sexes, the matrons and assistant matrons having had a general hospital training. He declared that the presence of women nurses in male wards had reduced the tendency to roughness and had brought an improved tone and atmosphere into the place. He kept one male nurse in each male ward to deal with any impulsive tendency. Women had more power than men in subduing excitement in male patients. These female nurses approached their work from the professional standpoint, and the elements which seemed to the layman unsuitable and were dwelt upon by him did not come seriously into the picture in the nurses' minds. Sexual perverts were separated from the generality of patients, and were looked after by men. The advantage of having female nurses on the male side was conspicuous therapeutically, he said. But able-bodied male patients were best looked after by men, as they could work with them on the farm and be companions for them in their amusements. Male nurses did not now resent being supplanted by women, and no male nurse had been discharged on account of the changed procedure; it was a case of waiting for resignations of male nurses to occur in the ordinary way. He agreed that the Union of Asylum Workers was opposed to the policy. It did not represent a financial saving, as the staff was now proportionally greater than at any previous period. That was especially so in the case of night staffs. There was now one nurse to about every eight patients, and seven doctors in the institution besides clinical assistants. Arising out of various questions, the witness said there were but few epileptics in Scotland; he objected to airing courts, as they seemed too much like a prison; he believed greatly in open-air verandahs and, except in certain cases, in unlocked rooms. There were no padded rooms at Morningside, and no need for them had arisen. In fact, just as restraint was practised less and less, so did the need for it seem to have lessened. Hyoscine should never be used as a continuous treatment, nor with the object of getting rid of all the excitement; but one dose was of the greatest benefit in stilling the initial mania and preventing much struggling. He also advocated a careful investigation in every case of the cause of an excited outburst, as he felt sure there always was a definite cause. He gave some interesting incidents which bore this out.

The Commission resumed its sittings on Monday, April 20th, the Chairman presiding.

Hospital Treatment of Mental Cases.

The witness in the morning was Dr. John D. Comrie, senior assistant physician to the Royal Infirmary, Edinburgh, who spoke of early treatment of mental cases at the infirmary. Mental cases had been treated at the infirmary since 1738, and the

Chairman read a minute from the records of that year which stated that as there was no proper place in Scotland for the care of lunatics, it was proposed to build five cells for their accommodation; this number was later increased to 12. In a certain proportion of cases in the infirmary there were mental symptoms, and from about 1813 a special ward had been set apart for them. Most of these cases at that date were alcoholics, and with the diminution in number of such cases, more room was available for other kinds of mental cases. The patients treated here were not certified, but were cases of ordinary physical illness in whom mental trouble had supervened, either at about the same time or at a subsequent stage. Often cases were so sent because their medical attendant was in a difficulty as to what should be done for them, and they were too noisy to keep in the home. The patients in this department came in voluntarily, and were under no legal restraint; from there they might be sent either elsewhere for convalescence, or transferred to the asylum. In the event of temporary mental aberration as in pneumonia, whatever physical restraint was necessary was exercised by the physician, and he took responsibility for it, and if the act of restraint subsequently came before a court of law the physician would probably be exonerated from blame. If such a patient were allowed up in these circumstances and it caused his death, a serious question as to neglect would have to be answered to the coroner. The patients in question were taken in and treated gratuitously, and this system, in very many cases, prevented patients from ever reaching the stage at which certification was necessary. Moreover, whatever surgical or special medical treatment was needed was available on the spot. Doctors outside showed a tendency to leave to the medical officers of the institution the question of certification. He only saw about 5 per cent. of the cases in the out-patient department before they actually entered the hospital. Some slight cases were treated in the out-patient clinic. Prof. Robertson intended to organise a psychopathic clinic. The visitation of friends here was on parallel lines with that in the general institution, and this had much influence in preserving the general hospital—as opposed to the asylum—atmosphere. In illustration of his view as to the restraint necessary, he said sometimes a patient with a fractured leg removed the splint and threw it under the bed, and raised the leg to look at it; and then it was necessary to fasten leg and splint to the bed, and limit the use of the hands. If human restraint were carried out, patients would continue to resist it, but they soon found it was useless to resist mechanical means, and soon desisted. Every effort was made to prevent noisy patients disturbing others. For this purpose it would be an advantage to have more rooms. 66 per cent. of the melancholic cases had attempted suicide before admission, but no such attempts were made while they were under care. In this department there were 24 patients, and for these there was a sister-in-charge, eight female nurses, and three male orderlies or porters. Special help in addition was always available.

Classification.

Sir Humphry Rolleston and Mr. Snell questioned the witness as to any detrimental effect on patients who needed all their nervous strength to recover from being in the same ward with noisy and more acute cases, and Dr. Comrie replied that this was so to some extent, but every effort was made to keep them apart and to diminish such risk. On the general run of cases, he said, in reply to a question by Sir Ernest Hiley, provision for 50 beds would suffice for Edinburgh. Most patients stayed about three weeks, they could be kept six weeks. In 1853 the alcoholic cases treated were 60 per cent. of the whole, and in 1923–24 this had fallen to 26 per cent., and the cases discharged sufficiently well to return home were 72 per cent. of the total, 17 per cent. being transferred to the mental hospital. Only five cases entered the mental hospital as voluntary patients. 66 per cent. of the cases of melancholia and depression had been so severe as to lead to attempts at suicide, but after a few weeks treatment 60 per cent. of them were well enough to return home, and many of them were cured, only 40 per cent., therefore, entering an asylum. But it must not be assumed that all the patients in that department were at any time certifiable. There were not many readmissions, and most of those were recurrent epilepsy. The types of cases which gave the best results were confusional insanity due to exhaustion or to toxic states, and the mental derangement occurring in the course of syphilis. Summarising his experience in a general way, he said that slight and undiagnosed cases of mental disorder admitted to a general hospital might be expected, in about 60 per cent. of cases, to recover sufficiently to return home after six weeks' treatment. Treatment in a general hospital was particularly valuable in expediting recovery because of the relative ease with which physical conditions (infective, exhaustive, or reflex) as partial causes could be discovered in a large proportion of the cases of confusional mental states, melancholia and psycho-neuroses. He also considered that the association of mental patients with those who were normal mentally in a general hospital expedited recovery and established public confidence.

Mr. Snell questioned the witness as to the reason for the decline in the alcoholic cases, and in his reply he said among the contributory causes were the high prices of spirits, the amount of unemployment, and the discipline which large numbers of the people underwent in the army. Still, the alcoholic cases were not now so severe as formerly.

Avoidance of Certification.

Dr. John Carswell was the last witness to speak on Scottish lunacy practice. He said he had been in practice and lunacy administration since 1878, mostly in Glasgow. He was now connected with the Ministry of Pensions in London. He said he was led to make his suggestion for the provision of treatment for early cases by the fact that systematised study of mental disorders was entirely neglected at that date until the patient actually had been certified and appeared at the door of an asylum. He strongly felt the need for placing incipient mental cases under care without the need of certifying them, in what had come to be known as observation wards. On account of the legal and other pitfalls connected with the subject there should be appointed for this work a medical officer who would be able to carry out his duties along the lines indicated. Out of the many thousands of cases which had passed through his hands while he held the office in Glasgow, the Parish Council had not to answer a single letter of complaint. The certifying doctor should, he thought, be a specialist in mental disease, but he did not suggest the general practitioner was inefficient. He attached great importance to visitation of the patient whose case was reported upon at his own home and in his ordinary circumstances and surroundings. In the later portion of his time at Glasgow, the population dealt with numbered 600,000, and 80 per cent. of the people were those who, if they had mental illness, would require public assistance. Cases reported by the inspector of the poor were, in most instances, seen by Dr. Carswell in their own homes on the same day. In reply to a question, he said his work was remunerated by a fixed salary; there were no fees. The 50 beds under his care at the Eastern District Hospital were at the date in question the only ones available for the kind of mental cases under discussion, and they were adequate for the cases then, as medical and public opinion had not been converted favourably to the idea. With regard to the question of detention of such patients, he agreed with the attitude of mind expressed by Dr. Comrie. If a patient expressed a determination to commit suicide at the first opportunity, Dr. Carswell said he would certify him in order to prevent this.

He preferred to do this rather than deprive the clinic of its valuable atmosphere of freedom. More than half the cases treated in this department for mental disturbance succeeded in escaping certification altogether.

Mrs. Matthews asked the witness whether there was any alternative available to reporting cases to the inspector of the poor, and he replied that he would much prefer that the doctor should report to the health authority, or, still better, to a mental board of health, as suggested by the Medico-Psychological Association. On the suggestion of Sir Humphry Rolleston he agreed to submit a memorandum on the subject.

PROCEEDINGS OF THE ROYAL COMMISSION ON NATIONAL HEALTH INSURANCE.*

(Continued from p. 840.)

EVIDENCE OF THE JOINT COMMITTEE OF APPROVED SOCIETIES.

Mr. F. W. Daniels, Chairman, and Mr. P. Rockliff, Secretary, gave evidence on behalf of this body, which consists (Q. 8015) of Associations of a specialised type—viz., Deposit Friendly Societies, Holloway Friendly Societies, Dividing Friendly Societies, the General Federation of Trade Unions, the Co-operative Group of Approved Societies, the Catholic Group of Approved Societies, and associations of small societies.

The Oxford Resolution.

(App. XIV., 3, 4. Q. 8023, &c.) A good deal of the evidence bore reference to a resolution of the National Conference of Friendly Societies, the Oxford Resolution, from which this Joint Committee dissociated itself. It was summed up by the witnesses (8024) thus: The merger of all existing forms of public medical service, including medical benefit under National Health Insurance, into one national medical service, thereby creating one unified organisation for the prevention and cure of disease. The witnesses considered that the—

> extension and administration of medical benefit as outlined in the Oxford Resolution . . . would lead . . . to an impression (in the minds of the patients, at any rate) that, as regards attendance, it was of the nature of a Poor-law medical service, and, as regards drugs, that they were of the "stock-pot" variety.

The misgivings as to the present medical service would, in the opinion of the Joint Committee, be considerably magnified in the system proposed.

(Q. 8160.) It was suggested that the executive of the National Conference of Friendly Societies which brought forward the Oxford Resolution were stampeded by Mr. Alban Gordon (whose evidence before the Royal Commission has recently been summarised in these columns).

The Panel Service and the Question of Extension.

(Q. 8026–41.) In the opinion of these witnesses, the panel service in the provinces, whilst not perfect, is reasonably efficient. As regards London, the service, in their view, is very far from being wholly satisfactory. The general trend of their evidence seemed to be that the London Panel Committee was to blame, and reference was made to the recent disputes in London about the action of the Medical Service Sub-committee.

> The Panel Committee in London seek to protect the scallywag, who, I have no doubt it will be said, will be found in all professions, and they carry it to extremes in London in changing their representation upon the Committee and in seeking to deprive the Medical Service Sub-committee of the judgment of an independent chairman.

Asked whether they would propose to scrap the Panel Service, and if not, what would be the alternative, they replied that they were hopeful that it might be still possible to improve the existing service. With regard to extensions of the Medical Service, the following rather cryptic statement is made:—

> (App. XIV., 24, 25.) The Joint Committee desire to see the benefit given by the Act of 1911 fully conferred upon the insured—i.e., "adequate medical attendance and treatment"—and not the restricted form of (domiciliary) medical benefit defined by the regulations. Given the former, there is no need separately to specify here the nature of the extensions desired in the latter.

No Free Choice under a Whole-time Service: The Regimentation of Women.

(Q. 8185–8200.) Asked why a whole-time service as contemplated by the Oxford Resolution should necessitate an allocation to one doctor without any free choice, and therefore involve what was described in the evidence as the "regimentation" of women, the witnesses said that that seemed to follow from the appointment of whole-time doctors for particular areas.

> If you are going to have so many whole-time paid medical men under a National Medical Service in any area as to give real freedom of choice, then you are going to make it financially impossible to set such a scheme on its feet.

Medical Benefit to Dependants not Recommended.

(App. XIV., 1, and Supplemental Statement.) The Joint Committee consider it undesirable to press at this present time for the extension of medical benefit to dependants of insured persons. They do not think that there is a clear demand for it from the insured persons themselves, and notwithstanding that "panel medical opinion has crystallised" in favour of such a scheme, they think that it is impracticable on financial grounds and also that it would throw an undue burden on the profession, especially in congested areas.

Petty Surcharges for Excessive Prescribing.

(Q. 8029.) Speaking again particularly of London Mr. Rockliff said:—

> As regards drugs, miserable petty surcharges have been made upon doctors because in their discretion, which would be unchallenged when dealing with a private patient, they prescribed a 5-grain pill and it was alleged—I am speaking from personal knowledge—that a 3- or 4-grain pill would have been as efficacious. It is a sin, too, for a flavouring essence to be put into an insured person's medicine. Insurance bandages too—I think it is altered now, but previously it was so—were to be drab or grey, not white as for a private patient.

Pooling of Funds.—Pure Theft.

(Q. 8179.) The pooling of societies' funds would, said Mr. Rockliff in one answer, be "pure unadulterated theft." (Q. 8244–8365.) The evidence generally suggests that there would be a clear breach of faith if any proposals were made to take the surpluses of the stronger societies and give them to the weaker.

> (Q. 8298.) The fact that by a selection on the part of the insured persons different results were going to accrue was patent to everybody in 1911. It was patent to trade unionists, and if they induced their members to segregate themselves in occupational societies, that was, at any rate, the result of their wrong advice.

As to this, it was suggested to the witness (Q. 8301) that 14 years' experience of fact might cause Parliament to alter a good deal of what in 1911 was simply theory.

---

* In previous articles the proceedings of the Commission were reported under the following headings: Introductory Note; The Scope of the Insurance Scheme (see THE LANCET, Jan. 31st, pp. 247–8); The Provision of Medical Benefit (Feb. 7th, pp. 301–3; Feb. 14th, pp. 355–6; Feb. 21st, pp. 403–5); Financial Provisions of the Act (Feb. 28th, pp. 454–7); Medical Certification and the Regional Medical Staff (March 7th, pp. 508–9); The Approved Societies and the Money Benefits (March 14th, pp. 564–5; March 21st, pp. 623–4); Evidence of the Hearts of Oak Society (March 28th, pp. 677–9); Evidence of the National Conference of Industrial Assurance Approved Societies and of the Manchester Unity Approved Society (April 4th, pp. 731–3); Evidence of Independent Order of Rechabites, of Rational Association Friendly Society, and of Miners' Societies (April 11th, pp. 784–6; April 18th, p. 839); Evidence of Mr. Alban Gordon (April 18th, pp. 839–40).

References to the printed statements issued as appendices to the reports of the oral evidence are given thus; Section A, para. 69, is shown as "App. A. 69," and references to the oral evidence thus—Q. 1369.

Additional Treatment Benefits.

(App. XIV., 26.) The Joint Committee are prepared to support the extension of the list of additional benefits so as to enable Approved Societies to make monetary grants to enable their members to secure massage, radiant heat, and other electrical treatment, blood tests, X ray, and similar advantages in dealing with illnesses. They are opposed, however, to any transfer of treatment benefits out of the hands of the Approved Societies.

> (App. XIV., 27.) As regards treatment benefits generally, whilst special considerations might be advanced in regard to a benefit given nationally as a normal benefit under the Act, the Joint Committee are opposed to any transfer out of the hands of members of Approved Societies of the administration of the present system of monetary grants in aid of treatment.

Dental Benefit.

(App. XIV., 28–31 and Supplemental Statement.) The only treatment which appears to the Joint Committee to justify an effort to secure it upon a national basis is probably dental benefit. Even then it would, it is believed, still be desirable for societies to continue to administer it. Such a benefit, if given nationally, would require to be given free of cost to the insured to enable the ill-paid, and not merely the well-paid, among the insured to obtain it.

In view of the possibility of the present valuation resulting in the very large surpluses which seem probable, it would appear that 100 per cent. dental service is not an impossibility, if preference is given to it over other additional benefits, and the Joint Committee are not impressed by the suggestion that the dentists available are inadequate, although (App. XIV., 43) this "might be true of qualified dentists."

In their supplemental statement of evidence (35), the Joint Committee say :—

> Should the surplus be found to amount (when the 1923 valuation results are known) to the figure now suggested, the Joint Committee would doubtless consider the desirability of utilising such part of that surplus as is requisite to provide a 100 per cent. dental service in priority to (*a*) a reduction in the weekly contribution, or (*b*) an increase to a limited extent in the normal rates of cash benefit, which were advocated in their original statement.

The Future of Insurance Committees.

(Q. 8724–5.) In later evidence on dental benefit, the witnesses said that the whole cost of this benefit might be estimated from the experience of some societies at from 5*s.* 6*d.* to 6*s.* 6*d.* per insured person—more probably the higher figure. If by making this a normal benefit is implied meeting the full cost of the benefit,

> and a member's medical card, for example, entitled him to go to both a dentist and a doctor, it certainly could be argued that Insurance Committees might be entrusted with the work; but if dental benefit as a normal benefit is anything short of a 100 per cent. service, in our judgment Insurance Committees are conclusively ruled out.

(Q. 8729.) With regard to the work of Insurance Committees generally, Mr. Rockliff said :—

> We are not here to press for their annihilation, but at the same time we do not lend any support to the effort to preserve their lives by stealing work which is being better performed by other persons at the present time.

EVIDENCE OF STOCK EXCHANGE AND LLOYDS' HEALTH INSURANCE SOCIETIES.

Evidence on behalf of these Societies was given by Mr. E. E. England and Lieut.-Commander E. G. Holdway, respectively.

Advocacy of Insured Persons Making Own Arrangements for Medical Benefit.

The principal matter upon which they made submissions to the Commission was as to the medical service.

> (App. XV., 6–8.) The Panel Medical Service has always been most unpopular with a large number of our members. We have had many complaints from insured persons who feel that they are not receiving the attention and treatment that was promised to them, that the doctors agreed to give, and for which the members have paid.

The witnesses advocated :—

> The continuance of the Panel Medical Service with an amendment of the Medical Benefit Regulations, to allow of the unrestricted right of every insured person to make his own arrangements for medical benefit with a doctor who is not on the panel.

The witnesses pointed out that although Insurance Committees have power to allow insured persons to make their own arrangements, the conditions are so strict that only a few cases are allowed.

(Q. 8455–80.) The witnesses were asked whether such an extension of the "own arrangements" method, as they suggested, would be consonant with the idea of insurance. They replied that the member would exercise the option, knowing perfectly well that only a portion of his doctor's bill would probably be met, and that the balance would remain for him to pay.

> I can see no reason why the principle of insurance should be incompatible with private arrangements. There are many insurance companies which issue policies against sickness, and the insured makes his own medical arrangements. There should be obviously a certain scale, and the member would know that he had to cover any excess from his private resources.

Although it was agreed that the majority of the doctors are on the panel, and that many of the doctors from whom members of these societies obtain treatment as private individuals, were nevertheless on the panel, it was thought that the fact of a doctor being under a contract of insurance made a marked difference in his outlook.

> (Q.) Your suggestion is that the doctor does not realise his responsibility to his patient ?—Yes. There is also the psychological aspect of it. The doctor knows he has a certain number of people on his panel for which he is going to receive a certain sum of money, and any extra private patient means extra money for him. He knows very well that he has had that income assured to him, and without wishing to say a word against the medical profession, there is the human element that naturally comes in. He may be tired, he may be overworked, but if a private patient comes and there is more money coming in, he gives that person better treatment. There is no doubt about it in many cases. I have had cases brought to me, and I am quite satisfied that there are many cases where they have had different treatment altogether.

With regard to the contrary suggestion that as regards his panel patients the doctor feels a greater responsibility, the witness replied :—

> I quite agree there is a lot to be said for your argument, but between that degree of neglect which a person may feel and the degree of neglect which one can bring before an Insurance Committee as a complaint, there is a very wide margin.

(Q. 8523.) The witnesses wished to avoid making sweeping charges against the medical profession and, indeed, they considered that the panel service was considerably improved.

> It is getting better and better. When the Act first came into force there was very great prejudice against it, and that still sticks in the minds of a large number of our members.

Other Treatment Benefits.

(Q. 8430–40.) The members of these societies are mainly selected lives, so that the societies carry smaller risks, and moreover a considerable number do not claim the ordinary benefits to which they are entitled during sickness. This enables these societies to give other very substantial benefits—e.g., full dental treatment, which includes examination, scaling and gum treatment, extraction (with or without anæsthetic), filling, stopping, crowning, and the supply of artificial teeth where needed. Also optical treatment; the members go to an optician in the City, and the full cost of pince-nez or rimless glasses or astigmatic lenses are allowed; gold frames, however, are not provided. The societies also provide medical and surgical appliances, either through the Surgical Aid Society or a private surgical instrument maker.

They would resent the loss of these benefits under a pooling scheme, and pointed out that city clerks have never yet been favourable to National Health Insurance, and it was important that nothing should be done to increase their hostility.

Evidence of the Group of Catholic Approved Societies.

For this group Mr. Joseph Moss and Mr. C. H. Waring gave evidence. (App. XVII.) This evidence comprised the following points :—

1. That there was an undue drain on the Benefit Funds owing to women members' claims before and after confinement, particularly in view of the lax way in which many doctors issue certificates for "pregnancy" and "debility following confinement" when the women to all appearances are not incapacitated from work.
2. That surpluses should be applied to treatment benefits rather than cash benefits.
3. That in meeting the cost of such treatment benefits there should be "voluntary coöperation between societies and branches, and that they were strongly opposed to Insurance Committees having the administration of these benefits.
4. That, as most of the cases submitted for examination arise from careless and unsatisfactory certification, the cost of the regional medical officers should come from the Benefit Fund.

The Personal Touch in Administration.

(Q. 8660–1.) The witness was asked what exactly was the personal touch in branch administration of which a member of the Commission said they had "heard such a lot" during the proceedings, and what it amounted to, if it could not be translated into actual cash or treatment. The witness did not attempt a definition. He said, however (Q. 8720), that under the branch system they were in fact in closer touch with the members than under any other system.

The Black Sheep.

As to the panel system generally, the main complaint appeared to be with regard to looseness of certification in certain cases, although (Q. 8676) the society felt such difficulty in preparing cases adequately for the Medical Service Sub-committee that they had not made use of the complaints machinery. It seemed to them that when society representatives got on to an Insurance Committee they lost their interest. By way of illustration, they suggested (Q. 8682) that many town councillors would be bankrupt in about a fortnight if they ran their own affairs as they run the affairs of the city.

(Q. 8705.) With regard to certification they said :–

> We have people coming on the funds through chronic bronchitis who come week after week for the benefit, and they are able to be out in all kinds of weather. We find that certain doctors specialise in a particular complaint. We know that in the case of one man nine-tenths of his certificates will be for rheumatism, and in the case of another man nine-tenths will be for bronchitis.

Generally, however, the doctors are trying to carry out their duties under difficult conditions, and it was to be expected that there would be some black sheep in the fold.

Ophthalmic Hospital of the Order of St. John of Jerusalem in England.—The report of this institution for the year 1924, signed by the Warden, Lieut.-Col. J. C. Strathearn, M.D., shows that the number of new patients seen was 16,225, and that of the total consultations 75,560. The number of patients admitted to the hospital was 1676 and the number of operations performed 4293. Among new cases the percentage of blindness in one eye was 8 per cent. and in both eyes 3·8 per cent., acute conjunctivitis being the most frequent cause, for during the year under notice the disease was widespread and virulent, though an improvement, now of five years' duration, was maintained. Trachoma, the chief scourge of Palestine, and largely associated with poverty and squalor, still shows a high incidence, and accounts for much of the work in the out-patient department, where the sufferers formed 83 per cent. of new cases. Until the social standards of the people are raised very little can be done for them in regard to this disease, but encouraging results follow the systematic treatment of children at school age. The majority of operations in the hospital, 66 per cent., was for the relief of trichiasis. The sanitation of the hospital is receiving the consideration of Dr. J. A. Henderson, the P.M.O., Jerusalem.

NOTES FROM INDIA.

(From an Occasional Correspondent.)

Coöperation and Public Health in Bengal.

An interesting method of combating malaria, as well as kala-azar and cholera, by means of coöperative public health societies has been put into practice with considerable success in the Province of Bengal, where malaria takes a heavy toll. The scheme originated with Dr. G. C. Chatterjee, formerly Assistant Bacteriologist to the Bengal Government, who in 1918 was able, in three villages which had been decimated by an epidemic of malignant malaria, to organise three Coöperative Anti-Malarial Societies and to get them registered under the Coöperative Societies Act. Subsequently he founded a Central Coöperative Anti-Malaria Society "to devise and carry out measures based on coöperative principles for the eradication of malaria from Bengal," which was registered and came into existence on June 5th 1919. The outline of the scheme is as follows. The Central Society exists to organise and create a network of Anti-Malaria and Public Health Societies on a coöperative basis throughout the villages of Bengal. Each of these societies is an autonomous body which raises funds by subscription from amongst its members. The Central Society acts as an advisory body to these rural societies, and may assist them financially. It places at their disposal the result of recent researches on malaria, kala-azar, cholera, and other preventable diseases. By February, 1924, as many as 129 societies had been organised. The anti-malaria measures which a society is required to carry out are: (1) filling up ditches; (2) improving drainage; (3) preparing a map of stagnant pools and regularly kerosinating them by volunteer help; (4) clearing undergrowth in the village; (5) administering quinine to all malaria cases in the village, and (6) keeping the fever index of the village systematically. Each society provides a duly qualified medical practitioner on a subsidy basis, whose duty it is not only to treat cases of illness, but also to instruct the people in preventive methods, and to establish a coöperative dispensary in the village itself or within easy reach of it. For organising public health societies and for educating their members, the Central Society carries out propaganda by means of magic-lantern lectures, leaflets, and a monthly journal, while the kinema and the stage are also pressed into service. The society is very strongly supported by the medical profession. Not only do the majority of its members belong to the profession, but it has also enrolled about 130 medical volunteers, at least half of whom are fully qualified practitioners, the rest being senior medical students. It enjoys good financial support, including a grant from Government, which in 1921 and 1922 was Rs.5000 and in 1923 Rs.10,000. The organisers of this system are to be heartily congratulated in their efforts to awaken the sanitary conscience of the village population of Bengal, and to promote the idea of self-help in local sanitation. It is to be hoped that such methods will in the near future be more widely extended throughout India.

Administration Report of Madras City for 1923–24.

This report is a somewhat belated document, but it contains details which are even now worth mentioning as Madras is the seat of Government and the premier city in the Presidency. The number of registered births was 22,925, giving a birth-rate of 44·6 per mille against an average rate of 38·8 for the previous decennium. As might be expected, there was the correspondingly high death-rate of 37·8 per mille, as compared with 42·7 for the previous year, and 46·6 the mean for the quinquennium ending 1922. In two divisions in the north of the city the recorded death-rates were 53·7 and 141·0 per mille respectively. It seems more than likely that in these areas the people are suffering from a recurrence of the malaria epidemic of 1912–13 which began in those same divisions. The death-rate from infectious diseases was 15·5 per mille, from dysentery and diarrhœa 7·2 per mille, while it is reported that small-pox, influenza, and relapsing fever were present only in sporadic form. Malaria is said to be responsible for 3·9 per cent. of the total deaths, a figure which has gradually increased during the last three years. About two years ago the anti-malarial staff, or the remnant of the staff left from 1912–13, was disbanded on grounds of economy. This step may prove to be a costly one to the corporation and the people. As regards child welfare work, a new centre was opened in the western area of the city and one more woman doctor was employed. Five pupils passed out of the school for health visitors, and the number of such visitors employed by the corporation rose from nine to 16. The midwifery service of the scheme continues to be popular, the total number of cases brought to the staff being 5820, as compared with 5549 in the previous year. The infant mortality-rate for the whole city was 254 per mille, which it is pointed out is the lowest ever recorded in Madras. The mortality-rate for children under the child welfare scheme was 202 per mille, but these two figures are neither of them matters for congratulation, and much more will have to be done before any remarkable reduction in the rates can be expected As regards conservancy, while the corporation has undertaken the private scavenging of a part of the city no appreciable improvement has been effected in the general conservancy of the town, and this branch of the administration requires closer supervision.

Bombay Children's Act.

Hitherto it has been a reproach to India that its protection of children was hopelessly deficient, but the Provincial Governments are now taking the matter in hand and a Children's Act has been drafted by the Bombay Government. The Bill proposes *inter alia* to make it an offence: (*a*) to be drunk in a public place while having charge of a child apparently under 7 years of age; (*b*) to give any child (except in case of sickness) apparently under the age of 7 years any intoxicating liquor; (*c*) to sell tobacco to a child or young person, and power is given to the police to seize any tobacco in the possession of a child or young person found smoking and to search any boy so found; (*d*) to incite or attempt to incite a child or young person to bet or borrow money, or to take an article in pawn from a child or young person.

National Health and Baby Week in India.

The health and baby week has been held for a second time, and it is probably correct to say that in recent years no movement has so quickly and successfully caught the imagination of the people. From Delhi, where Lady Reading opened the exhibition and baby show, and all over the country reports have been received demonstrating the success and the enthusiasm with which the week was celebrated. Each province was permitted to fix its own dates for the week to suit local conditions. Large sums of money were subscribed all over the country for prizes and for feeding the mothers and infants attending the celebrations. Last year the first baby week in India was held, and there can be no doubt that this year has easily eclipsed the efforts of 1924. The problem of carrying out health propaganda work amongst a conglomerate population such as one finds in India is an enormous one owing to the expense of preparing every leaflet and every poster in a dozen or more languages, but a very good start has been made, and if only more money were available a great deal more could be done as most local governments are in entire sympathy with this kind of work.

PARIS.

(FROM OUR OWN CORRESPONDENT.)

Bayer "205" and Sleeping Sickness.

Dr. Tanon has recently communicated to the Academy of Medicine the results obtained on an expedition to the Cameroons to investigate the treatment of human trypanosomiasis with Bayer "205." While admitting that the value of this product as a trypanosomicide is at least equal to that of other substances at present in use, he considers that the German preparation is not so innocuous as has been stated, for it has been found to have a toxic action on the renal epithelium. It causes albuminuria, which, although in most cases it clears up spontaneously, may lead to death from uræmia. The effect of the drug is to cause the trypanosomes to disappear very rapidly between the third and the twenty-fourth hour after the first injection. They do not reappear in the majority of cases, but some relapses have been recorded. The cases of relapse persist for a fortnight, then the parasites disappear again and do not return. Bayer "205," therefore, is not a definite cure, at least in human patients. It has no action on the parasites in the cerebro-spinal fluid when the nerve centres have been attacked, unless an intra-spinous injection is carried out, which is not a procedure to be recommended. In brief, Bayer "205" has not been found, at the present time, to be superior to other drugs in actual use, so far as human infection by *Trypanosoma gambiense* is concerned. Further, the criterion of a drug which claims to cure sleeping sickness must be its power to cause a meningeal lesion to disappear —that is to say, which can cure patients in the third stage of the disease.

A Small Epidemic of an Undefined Nature.

Several doctors of the Pas-de-Calais have recently observed, in one of the devastated regions of that department, a small epidemic of a malady which they have not been able to classify. Twenty definite cases were recorded a week after the first case was observed. The illness commences abruptly, the patient complaining of tiredness, headaches, and giddiness. Occasionally consciousness is lost, the respiration becomes rapid, the appearance haggard, and nervous twitchings occur. Then an eruption appears in the form of extended red patches, slightly raised and separated from each other by areas of healthy skin. These patches, which are erythematous but not pruriginous, are transitory, and a few hours after their disappearance small vesicles filled with a clear liquid take their place, which in turn dry up and form little epidermal flakes. The eruption definitely disappears within three or four days and leaves no trace. A very slight degree of fever is present. The majority of the patients were glaziers working in the neighbourhood of a carbide factory, where a lime kiln is in operation. The symptoms which have been observed do not seem to be caused by any poisoning arising out of the patients' occupation, nor can they be traced to the drinking water or to food. It is a question whether it may be an abnormal type of influenza, or whether the malady bears any relationship to hiccup or to encephalitis lethargica, all of which are prevalent just now in that area.

Hygiene and the Budget.

At the instigation of Dr. Léon Bernard, professor of hygiene at the Faculty of Medicine of Paris, the Academy of Medicine has protested against the reduction of monies available for public health purposes which was recently proposed by the Government, and the following resolution has been passed unanimously: "The Academy of Medicine, concerned at the proposed reduction of 132 million francs in the Public Health Estimates, considers it necessary to direct with some insistence the attention of public authorities to the disastrous consequences which such a measure would entail, the effect of which would be to impair seriously the initiative of public and private health organisations which have already produced tangible results in the fight against tuberculosis, syphilis, and infantile mortality. This apparent economy would be more than counterbalanced by a heavy loss in human life and an acceleration of the depopulation of France."

IRELAND.

(FROM OUR OWN CORRESPONDENT.)

Irish Medical Committee.

AT a recent meeting of the Irish Medical Committee a resolution was passed by a large majority in favour of the continuance of the Medical Register as at present. A discussion took place in regard to the inadequacy of the fees given for the registration of births, deaths, and marriages. In most districts in Ireland the Poor-law medical officer is registrar, and the fees allowed are 1*s.* for each entry of a birth or death, and 6*d.* for an entry of a marriage. These are much less than the fees allowed in Great Britain for similar duties. Recently registrars have been invited to undertake additional clerical duties without additional remuneration. The Committee passed a resolution asking the Registrar-General to take the necessary legislative steps to have the fees for the registration of births, deaths, and marriages increased to 3*s.* for each entry. Resolutions dealing with the appointments of surgeons to county hospitals were passed as follows :—

(*a*) That the minimal salary for a county hospital surgeon be £1000 per annum.

(*b*) That the county surgeon should be permitted to engage in consultative practice only.

(*c*) That in both county and district hospitals only patients for whom the State is statutorily responsible should be admitted for treatment.

(*d*) That if private patients are admitted they should be treated in a hospital apart from those entitled to treatment by the State, and that their private medical attendants should have the right to attend such patients with the county surgeon.

The Committee also reaffirmed its adherence to the British Medical Association scale of salaries for whole-time medical officers engaged in public health work ; and it asked for the early publication of the interim report of the Committee of Inquiry into National Health Insurance and the Medical Services.

The Irish Free State and the Medical Register.

The Minister of Local Government and Public Health recently invited representatives of the licensing bodies and of professional organisations in the Irish Free State to meet him in conference to discuss the measures that should be taken to provide for the future control of the medical profession. Mr. Burke (the Minister) pointed out that the present Act would run only until February, 1926, and he invited the opinions of the members of the conference as to the nature of the legislation that should take its place. Those present were unanimous in urging that the existing status should not be disturbed, and that the Government of the Irish Free State should exert itself to ensure that a common register for Great Britain and Ireland should be maintained as hitherto. Mr. Burke expressed himself as in accord with the views of the conference, and stated that he would put these views before the Executive Council. He asked that a small consultative committee might be appointed by the conference to assist him in matters of detail as occasion might arise. The following were then nominated as a consultative committee : Senator W. O'Sullivan, Sir James Craig, Mr. T. Hennessy, Mr. R. C. B. Maunsell, Prof. A. F. Dixon, Dr. D. Coffey, and Dr. E. Magennis.

"Audi alteram partem."

THE GOLD TREATMENT OF TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—On reading the preliminary report by the Medical Research Council on this treatment, published in your issue of April 18th, I cannot help making comparisons with the results obtained by the use of tuberculin when it was revived 10 or 12 years ago, and especially in cases where reaction-producing doses were used. By the latter method many strikingly successful results were obtained, but as soon as the "reaction" method became used for the treatment of patients in dispensaries it fell into discredit, and deservedly so. When used under strict sanatorium conditions the reactions usually subsided in a few days and no very unpleasant sequelæ were produced as a rule ; certainly none comparing with the severe jaundice or continuous hiccough described as occurring during the "gold" treatment. Nor were the cases of uncontrollable reactivation of the disease at all frequent when the patients were kept absolutely at rest during the reaction. One might reasonably suppose that if the 30 cases treated by "gold" had been intelligently treated by tuberculin reactions, the results would have been better. The use of tuberculin without reactions might have given even better results without the disasters if persisted in for a longer period.

In the treatment of tuberculosis the purely academic scientific atmosphere is not the ideal one for obtaining good results. In the hands of a sceptic everything fails except perhaps artificial pneumothorax now and then. The psychic effect of any new remedy is usually a favourable one, but one feels that during the gold treatment reaction stage many of the patients must have had their faith sorely tried, especially the exfoliative dermatitis victims. Some years ago I used a solution of normal saline and 0·5 per cent. carbolic acid, and in order to produce an exactly equivalent psychical atmosphere, called it a new tuberculin (O.K.) so that staff and patient were deceived. A course of injections in a series of patients was given, and four out of eight claimed a definite improvement (and showed it), two were uncertain, and two definitely negative. Probably the same result would have occurred with high dilutions of any tuberculin.

I think that the discrepancies noted amongst different workers can be accounted for by the difference in the psychical atmosphere in which the remedy was used and the type of case treated.

My point in writing this letter is to express the hope that a drug with such dangerous possibilities as sanocrysin will not be launched on the profession as a remedy without more experimental work than it has received at present.

I am, Sir, yours faithfully,
W. C. FOWLER,
Medical Superintendent, Pinewood Sanatorium.
Wokingham, Berks, April 20th, 1925.

To the Editor of THE LANCET.

SIR,—The preliminary report of the Medical Research Council on the treatment of tuberculosis by "sanocrysin" (THE LANCET, April 18th, p. 833) is not of such a nature as to encourage either physicians or patients to try this so-called therapeutic agent. The benefits obtained are very doubtful, and benefit, when obtained, can be easily explained on the assumption, which seems to be warranted from the clinical histories of these patients, that this substance has the power of causing focal reactions, which, as is well known, may in a few suitable cases produce benefit. The same thing happened during the tuberculin period, but the harmful results in the case of the gold preparation are much worse, for besides causing an increase of the disease this preparation seems to be a deadly poison.

There seems to me to be some confusion of thought shown in the method of approaching this problem. I understand that the idea of Prof. Möllgaard is to provoke a reaction in the tuberculous lesion with the hope that some kind of repair may take place, presumably by fibrosis, for it is very dangerous to try and produce exfoliation in pulmonary tuberculosis unless the disease is very limited. In order to mitigate too great a toxæmia I understand that an anti-serum has been prepared to neutralise the effect of the toxins produced at the site of the lesion. We who have been engaged in sanatorium treatment for many years have been for the most part engaged in trying not to rouse up lesions to greater activity, but to try by rest and other means to reduce the toxæmia. It has occurred to me that in conducting a research of this kind it would be well first of all to try this serum upon cases which have not been subjected to the gold treatment, but which are already toxæmic, for if it should be found that toxæmia could be controlled we should have one of our chief difficulties removed. I would observe in passing that when any substance which has the capacity to stir up lesions is being used when a reaction has been produced, the remedy must be stopped forthwith, and if after the reaction has passed off the patient is worse, which, in my experience, is generally the case, then the remedy should be stopped at once.

I would suggest that if this method of treatment be persisted in, the dose be reduced a hundred times at least, the intervals lengthened, and a rectal temperature be taken in every case both during and before the administration of the drug. We have found here that T.R. given in dilutions of 1 in 100,000,000, commencing with 0·1 c.cm., are quite safe and have in a considerable number of cases the power of reducing the fever of persistently febrile cases, the dose and the intervals being gauged by a carefully taken rectal temperature. The same is true of colloid of calcium, in which an efficient dose in some cases may be as small as 1000th of a grain and which may produce a reaction in certain cases. In ordinary surgical tuberculosis the dose may be much greater because there is not the same liability to toxæmia. If this is true of a comparatively harmless preparations such as calcium it may be much more so of a drug such as "sanocrysin."—I am, Sir, yours faithfully,

EDWARD E. PREST.

SCARLATINIFORM RASHES IN INFLUENZA.

To the Editor of THE LANCET.

SIR,—The difficulty which besets the diagnosis of scarlet fever appears to me to increase year by year. To the public, scarlet fever is still, and perhaps rightly so, a bogey—they associate it with a long period of isolation, strict quarantine, acute ear disease, perhaps followed by permanent deafness and other serious complications. For this reason the diagnosis of scarlet fever by a general practitioner is made with considerable anxiety unless it is an absolutely typical case. If the practitioner happens to be associated with a boarding school his anxiety about the diagnosis is probably greater, because when it becomes known that a case of scarlet fever has arisen at a school, it may do that school considerable damage, and cause great worry to the staff and also perhaps more so to the parents of the scholars.

The difficulty in diagnosis has recently been brought home to me by four cases, boys at a boarding school, whom I have recently had under my care. These cases arose during an epidemic of influenza (90 cases out of 120 boys). Three of them developed a scarlatiniform rash, simultaneously, with an increased rise in temperature, five or six days after they had been taken ill with the influenza. The rash appeared on the trunk only, the influenza was associated with sore-throat and catarrhal symptoms, so it was difficult to say if there was any increased redness of the pharynx. The rash disappeared in three days, and there were no complications. The medical officer of health who saw the cases with me preferred to express no definite opinion, but advised me to isolate the cases and wait and see what happened. At the end of 18 days, no complications having arisen and no desquamation of any sort having appeared, I thought it safe to let the boys out of isolation. One of them who went home promptly started to desquamate; the other two have had no signs of desquamation. The other case during the same epidemic developed a scarlatiniform rash, which lasted two days; he had an increase in the soreness of his throat, and developed a quinsy. This case was much less like scarlet fever than the others, yet he eventually developed typical desquamation of the hands and feet. I have recently seen it stated that the rash of scarlet fever has to be diagnosed from a rash due to influenza. Were the rashes I have mentioned scarlet fever rash or due to influenza?

I should like to know if other medical men have met with any similar cases during the present epidemic of influenza. The recording of the cases, I am sure, would be of value in the differential diagnosis between scarlet fever and influenza.

I am, Sir, yours faithfully,

CHARLES BIRCH.

Whitchurch, near Reading, April 17th, 1925.

NURSING HOMES (REGISTRATION) BILL.

To the Editor of THE LANCET.

SIR,—May one use your columns to draw the attention of the profession—more particularly consultants and those who receive one or more patients into their private houses—to this Bill, which has had its first reading? It is backed by the College of Nursing and Lieut.-Colonel Fremantle, M.P. (late M.O.H.), amongst others; and they are now urging that it should be adopted as a Government measure. In its present form it would extend into the private homes of doctors the inquisitorial supervision and disciplinary regulations of the Ministry of Health, with consequential fines and penalties, so well known to insurance practitioners in their domiciliary practice. It is another instance of proposed legislation by regulations.

The definition of a nursing home is given as "any premises . . . for the reception of . . . persons suffering from any sickness, injury or infirmity for the purpose of the provision of such persons with . . . food either with or without medical . . . and where any payment . . . is made." This definition includes, and I have been informed is intended to include, doctors who receive patients of any kind. Patients who are placed, or place themselves, under the care of a doctor desiring to be associated in the home life are readily divided into four groups—namely, certified, border line, drug addicts, and those suffering from chronic forms of illness more peculiarly affecting the aged. Every doctor who receives any such patient would be subjected to the conditions outlined in this Bill if it passes in its present form.

These conditions include determination by the Minister of Health: (*a*) whether the doctor is a suitable person to receive one or more patients; (*b*) whether the nurses and servants he has engaged are suitable; (*c*) whether the lighting, heating, ventilation, and sanitary state of the accommodation for the patients, nurses, and servants are satisfactory; (*d*) whether the home is properly equipped for patients; (*e*) the exact prominent position in the house where a copy of the regulations shall be displayed for all to read; as also the exact position inside and outside the house where a notice shall be placed that the house is a "registered nursing home." Also the medical officer of health or an appointed State registered nurse, at reasonable hours, can call to inspect the whole house and staff, the entries and records in the registers of patients, of transfers and discharges, of deaths, of clinical records, of dispensing done, of casualties, as also the reports required to be made from time to time.

Now the primary object of receiving these patients into a doctor's house is to provide for them the atmosphere of a home, whilst insuring that care and supervision by a doctor so necessary if any improvement in their health is to be hoped for. If this Bill goes through in its present form then consultants and private practitioners will find themselves deprived of just those non-institutionally conducted homes which their patients require; for there can be no question that private practitioners who at present receive these patients will refuse absolutely to place their homes, themselves, and their families in a position to be dragooned by a State organisation. That result would be against the interests of the public, the patients concerned, the relatives, and the medical profession generally. It has been said—and by doctors—that if the notice board outside the house is done away with there is nothing to object to! This shows lack of vision. Also that doctors must not expect to be treated differently from any lay person who may decide to open a home! Surely the profession is sufficiently dominated at the present time by the State. Will it tamely allow this further proposal?

May I urge all interested to at once read the Bill, and then to communicate their views to their Member of Parliament, the British Medical Association, as well as to any others whose influence could be brought to bear in order that the members of the medical profession who receive private patients be excluded from the operations of this Bill? Unless this condition is secured the Bill should be opposed with all the power still left to us. There is no time to be lost.

I am, Sir, yours faithfully,

Hove, April 18th, 1925. E. Rowland Fothergill.

HOW TO BLOW THE NOSE.

To the Editor of The Lancet.

Sir,—With reference to Dr. A. D. Sharp's letter on this subject in your issue of to-day's date, I would like to say that it is important that the child (or adult) should be taught to blow *into* the handkerchief and not against it, as is so usual, also to grip the upper or bony part of the nose and not the cartilaginous, so avoiding any artificial increase of intranasal pressure. This advice is especially necessary after nasal douching. Further, when there is perforation of the tympanic membrane the raising of pressure is especially to be avoided, and where the Eustachian tube is freely patent the patient should be warned to prevent the rush of air and mucus into the middle ear by blocking the external auditory meatus with the finger or thumb of the unoccupied hand.

Parents should be advised to see that children use their noses for respiration at all times, especially after operations for the relief of nasal obstruction, so that the organ may become developed for the purpose for which it is intended.

I am, Sir, yours faithfully,

London, April 18th, 1925. C. Hamblen Thomas.

UNIVERSITY OF LONDON SENATORIAL ELECTION: TWENTIETH CENTURY SOCIETY OF LONDON GRADUATES.

To the Editor of The Lancet.

Sir,—My attention has been directed to a paragraph in the issue of The Lancet for April 18th which implies that the Twentieth Century Society of London Graduates stands for the adoption of the Haldane Report. This is not correct.

The principles underlying the evidence which will shortly be submitted, on behalf of the Society, to the Departmental Committee on University Education in London are as follows: (1) Government of the University by a representative Senate as at present, and not by a Senate mainly nominated as suggested in the report of Lord Haldane's Commission. (2) Adequate representation on the Senate of teachers, graduates, principal colleges, and contributing authorities. (3) A large measure of college autonomy in finance and administration. (4) Maintenance of the external degree. (5) Recognition of the position of teaching institutions outside London preparing for the external degree and systematic consultation of them with reference to curricula and examinations.

In fairness to Mr. T. B. Layton, the candidate who is being supported by the Society at the forthcoming Senatorial election for a Convocation representative of the Faculty of Medicine, may I ask you to insert this letter.—I am, Sir, yours faithfully,

G. F. Troup Horne,
Hon. General Secretary.

Malet-street, W.C., April 21st, 1925.

Public Health Services.

REPORTS OF MEDICAL OFFICERS OF HEALTH

Borough of Hornsey.

The first annual report for the year 1924 to reach us is that in which Dr. A. T. Nankivell deals for the last time with the health of Hornsey before taking up his new duties at Plymouth.

Most of the health statistics of Hornsey for 1924 are favourable. The population is estimated at 88,661. The birth-rate was low, 15·0, attributed by Dr. Nankivell to late marriages, to birth control, and to the practice of various methods for procuring abortion. The dozen instances of the latter brought to his knowledge only give a slight indication of the prevalence of this practice. The death-rate from all causes was 10·4, and a lower death-rate is hardly to be expected in this district, owing to the excess of elderly persons in the population. The infant mortality-rate was by far the lowest on record—namely, 36 per 1000 births. The lowness of this rate draws attention to the fact that the neonatal rate shows no tendency to decrease. No less than 34 of the 48 infant deaths occurred during the first four weeks, and an interesting chart given by Dr. Nankivell shows that the neonatal mortality-rate has remained constant during the last 40 years, whilst the rest of the infant mortality-rate has declined in a remarkable manner. In view of this, Dr. Nankivell urges the importance of skilled medical advice during pregnancy. The total tuberculosis-rate for the borough was 0·67, while the cancer death-rate gave the high figure of 1·7. There were two maternal deaths from childbirth, which is equivalent to a rate of 1·5 per 1000 births. The death-rate from respiratory diseases and influenza was 2·0. Heart disease and nephritis caused nearly as many deaths as cancer, and Dr. Nankivell suggests that as diseases of the arteries, heart, and kidneys yield very well to care and early treatment, it would be well if the custom of a periodical overhauling, as is usual in the case of our teeth, were applied to these organs.

Dealing with the milk-supply, Dr. Nankivell draws attention to several objectionable practices. Milk which has been round the streets on a barrow may be reheated and placed in cold storage and subsequently sold as fresh milk. Some pasteurised milk may be sold as "fresh" milk or "new" milk or "milk," and the obligations of the seller of pasteurised milk thus avoided. One example is quoted of a milkman who has a pasteurising plant but does not use it invariably, and sells his produce as "milk." Dr. Nankivell points out that a milkman may be licensed to sell pasteurised milk, that he may have a suitable pasteurising plant, and that he may put the milk through the plant, lay it down in cold storage, and retail it at his convenience "under the engaging title of new or fresh milk." A most objectionable practice mentioned is that of the milkman who fills up from a churn on his barrow dirty bottles taken from doorsteps and forthwith redistributes them to his customers.

In connexion with the maternity and child welfare scheme, three massage clinics have been arranged by the voluntary committee and are doing useful work. Dr. Nankivell hopes that the provision of a convalescent home for mothers and babies will be one of the next departures. Hornsey being mainly a residential town of good-class houses, there are no slum areas, but there is a good deal of overcrowding of several families under one roof. This overcrowding is economic in origin, and will not be remedied by the council's new houses, although the latter are eagerly sought by those who can pay a reasonable rent for a good building. In his school report Dr. Nankivell says it is difficult to see the results of a slowly operating system, but that the older teachers are unanimous in appreciating the difference between the school child of to-day and the child of 15 years ago. In Hornsey there is not much malnutrition caused by lack of food, but there is malnutrition caused by the wrong choice of food. "Bread and jam, cakes and sweets too often form the bulk of the diet of the growing child; the entire absence of fresh foods from many dietaries is deplorable. Even if a man has an allotment and grows his own green vegetables, his family does not seem to eat lettuces, mustard and cress, or cabbages; tinned milk is often used instead of fresh milk, and canned fruits and fish instead of the fresh articles." "The remedy," says Dr. Nankivell, "lies in the education of the parents and especially of the children themselves; and girls at cooking classes should learn not only how to cook but also what to cook."

INFECTIOUS DISEASE IN ENGLAND AND WALES DURING THE WEEK ENDED APRIL 11TH, 1925.

Notifications.—The following cases of infectious disease were notified during the week, namely:—Small-pox, 149; scarlet fever, 1568; diphtheria, 769; enteric fever, 35; pneumonia, 1318; puerperal fever, 51; cerebro-spinal fever, 10; acute polio-encephalitis, 1; encephalitis lethargica, 48; continued fever, 1; dysentery, 19; ophthalmia neonatorum, 98. There were no cases of cholera, plague, or typhus fever notified during the week. The number of small-pox cases showed a decrease of 3 from the number for the preceding week. Twenty-six cases were notified from Derbyshire (Derby C.B., 15); 19 from Northamptonshire (Kettering, 15); 20 from Northumberland; 23 from Notts (Mansfield Woodhouse, 10); and 41 from Yorks, North Riding (Middlesbrough C.B., 40).

Deaths.—In the aggregate of great towns, including London, there wese 4 deaths from enteric fever, 143 from measles, 17 from scarlet fever, 125 from whooping-cough, 36 from diphtheria, and 221 from influenza, as compared with 242, 281, 304, and 283 in the four preceding weeks. In London itself the deaths from influenza numbered 31, from whooping-cough 33, and from diphtheria 8.

THE LATE DR. E. C. PRICHARD.—Evan Christopher Prichard, M.D. Edin., of Horse Fair, Banbury, died on April 8th at the age of 47 following an operation. He was a son of the late R. K. Prichard, of Bridgend, and received his medical education at Edinburgh University, where he qualified M.B., Ch.B. in 1902, obtaining the M.D. four years later. After holding the usual hospital appointments, he took up practice in Banbury, where at the time of his death he was senior honorary medical officer to the Horton Infirmary. A colleague writes of him: "Prichard was one of those men to whom his patients' illnesses and troubles were his own anxiety throughout. He engaged in all branches of practice, but it was as a surgeon that he did his best work. He possessed that essential quality of a good surgeon, the ability to do the right thing in an emergency. In his dealings with his colleagues his most lovable characteristic was his boyishness, his open heart, his cheerful and direct speech. It is with feelings of great regret that his colleagues in this district look upon his untimely death when much of his life's work lay in front of him."

Obituary.

SIR RICKMAN JOHN GODLEE, BART., K.C.V.O., M.B., M.S. LOND., F.R.C.S. ENG.,

CONSULTING SURGEON, UNIVERSITY COLLEGE AND BROMPTON HOSPITALS; LATE PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

WE deeply regret to announce the death of Sir Rickman Godlee, which occurred at his house, Coombe End, near Whitchurch, on Monday last, after an illness of only a few hours.

Rickman John Godlee was born of an old Quaker family, the son of a barrister whose wife was sister of Lord Lister, and Godlee's relationship to the discoverer of antiseptic surgery had a paramount influence upon his career. He was born at Upton, Essex, on Feb. 15th, 1849, and was brought up in the usual environment of a prosperous Quaker family. He received his early education at a school at Tottenham mainly supported by the Friends, where natural history formed a definite and even a large part of the curriculum, so that from his youth he was a field botanist and ornithologist, and able to draw lessons from the biology of the countryside. He graduated at the University of London at an early age, and entered University College Hospital as a medical student, where he was remarked as an able anatomist. He qualified as M.R.C.S. Eng. in 1872 and filled the usual house appointments at the hospital, while he studied for the London degrees in medicine and surgery, being awarded the gold medal for surgery. He then went to Edinburgh, where Lister's work was proceeding and where the significance of the great discoveries had been more fully recognised than it was in London. Here he worked with Lister as an assistant and acquired full knowledge of the theory and technique of antiseptic surgery as practised in those early days, and on returning to London became surgical registrar at University College Hospital. In 1876 he took the Fellowship of the Royal College of Surgeons of England, and was elected assistant surgeon to Charing Cross Hospital and the Queen's Hospital for Children. In the following year a vacancy occurred on the staff of University College Hospital, and he was elected assistant surgeon at the hospital, becoming, as was the usual practice in the London schools of medicine at the time, demonstrator of anatomy in the medical school. The staff on the surgical side of the hospital was strong, including Erichsen, Henry Thompson, John Marshall, Berkeley Hill, Christopher Heath, and Marcus Beck, the last being Godlee's cousin, immediate senior and the colleague with whom much of his work was done. As a demonstrator of anatomy Godlee, in addition to his wide knowledge, had the great advantage of being a brilliant draughtsman, who was responsible for many of the illustrations in one of the issues of Quain's Anatomy.

Godlee's career as a hospital surgeon and consultant was quietly successful throughout. He was known to be the constant assistant to Lister in his operative practice in London, where the great surgeon was now living and attached to King's College Hospital; his colleagues and his students learned from the first to appreciate his wisdom and his skill. His name came prominently to the front in connexion with a case of excision of a tumour from the brain. This case created keen interest some 40 years ago and a full account of it will be found in our columns.[1] The patient, a man of 25, came to Hughes Bennett, a leading neurologist of the day, complaining of paralysis of the left arm, complicated with a vague story of injury on the same side of his head. Symptoms of cerebral irritation had occurred for more than two years, and finally there were seizures with loss of consciousness about once a month. When the patient came under observation he was being attacked with spasmodic twitchings of the left hand and arm, which alternated with twitchings of the face; he had paralysis of the upper limb, but general health and intelligence were good, pains in the head being the main thing of which he complained. Hughes Bennett from all the symptoms diagnosed a tumour in the cortical substance in the neighbourhood of the upper third of the fissure of Rolando, and Godlee was selected to cut down at that spot with a view to any necessary operation. The risks of an operation which was an innovation were explained to the patient who cheerfully submitted with the hope of relief from intolerable pain. Godlee removed a triangular piece of bone over the indicated area, found the ascending frontal convolution distended, made an incision some quarter of an inch below the surface, and discovered a glioma about the size of a walnut, which he enucleated. For a time the operation appeared to be entirely successful, but subsequently the patient died of secondary surgical complications. The account of the case in THE LANCET attracted much public attention, and led to a discussion in the *Times* on the subject of vivisection, the suggestion apparently being that a human patient had been made the subject of a surgical experiment. Accordingly the whole case was discussed at the Royal Medical and Chirurgical Society, when Hughes Bennett described the operation, its termination, and the post-mortem findings, discussing the physiological and pathological points of interest. Sir David Ferrier, Hughlings Jackson, William MacEwen, and Victor Horsley took part in a debate which abundantly proved that, in spite of its unfortunate issue, the case was one of the highest importance, as it substantiated the well-known researches of Hughlings Jackson and Ferrier, and established the possibility of surgical relief for cerebral growths.

---

[1] THE LANCET, 1884, ii., 1090.

SIR RICKMAN GODLEE.

[*Photograph by Elliott and Fry, Ltd.*

In 1884 Godlee was elected surgeon to the Brompton Hospital, with which institution he was connected actively for over 20 years, and where he did some of his best known work. Its results are modestly but accurately represented in the well-known volume on "Diseases of the Lungs" written by himself and Sir James Kingston Fowler. This work was immediately recognised to constitute an important addition to the literature of scientific and practical medicine, while it brought home to the profession in a striking manner what an extension of the surgical province had been provided by the development of antiseptic surgery and of bacteriology. The work was one of real coöperation between the authors, the contributions of each being studied by the other; it was the outcome of long joint experience at the Brompton Hospital, and the valuable aid of other members of the staff, notably of Dr. Percy Kidd and Dr. A. F. Voelcker, was received throughout. The orderly arrangement of the treatise, the precise statements where possible, and the omission of dogmatic assertions, as well as the wide range of material, marked the book off for immediate success, while Godlee's chapters on the surgery of the lung and pleuræ became an inspiration to operators, all the more forcible because the clinical teaching was accompanied by an admirable chapter on the anatomy of the parts concerned.

Godlee's long and distinguished connexion with the Royal College of Surgeons of England began by election to the Council in 1897, but he had previously examined for the College, ultimately becoming chairman of the Court of Examiners. In 1911 he was elected President in succession to Sir Henry Butlin, who died during his term of office, and he presided over the College for the three years preceding the war, discharging the duties with the punctilious and quiet completeness that were anticipated by all who knew him. He delivered the Bradshaw Lecture of the College in 1907, taking as his subject the surgery of tuberculosis of the genito-urinary organs, and was Hunterian orator in 1913. In 1912 he was created a baronet, and was made a K.C.V.O. in 1914 on the termination of his office. He was surgeon to the Household under Queen Victoria, and later Surgeon-in-Ordinary to King Edward VII., and to King George V. One of his last acts in office at the College was to go to America to deliver an address on the occasion of the foundation of the American College of Surgeons, of which he became an original Fellow. In this address he briefly reviewed the history of the College, its rise from a city company, its evolution into a Royal College, its relations with the Royal College of Physicians, and its double function as a great examining body and the trustee of the Hunter Museum. There is no doubt that the clearness of the address, and the spirit of brotherhood displayed throughout in its expressions, formed a valuable link on the eve of war between the medical activities of the two countries.

When the war broke out Godlee was too senior to serve in any consultant capacity abroad, but in many ways, and always unostentatiously, he worked to maintain our medical efficiency in all spheres. He was a punctilious member of the Central Medical War Committee, and in the early days of that Committee his shrewd and tolerant advice as to the methods by which our armies abroad could be adequately supplied with medical officers, without over-depletion of the medical service at home, was on all occasions accepted. He was also chairman of the Belgian Doctors' and Pharmacists' Relief Fund, and in that capacity served continually on a Committee which sat monthly for some two years in the offices of THE LANCET. The Editor of THE LANCET was secretary of the movement, and Dr. Harold Des Vœux was treasurer, and the subscriptions, as they were contributed in open-handed manner by the medical profession, were immediately devoted to relieve distress in suitable cases. The responsibility for the individual grants was taken by the three officers of the fund, and every day for many weeks Belgian refugees belonging to one or other of the professions were interviewed and grants were made which, during 1915, formed the only source of support for many of the miserable families. Godlee was instrumental in bringing to the notice of the General Medical Council the advantage of sanctioning the practice of allowing Belgian practitioners to qualify in England, when an appreciable number were placed in a position of earning their own living, while others were supplied with money and facilities, in order that they might join their own fighting forces on the Western front. By the beginning of 1916 it became possible to relieve the medical men and pharmacists in Belgium itself, and for some months money was sent at the rate of £100 and later £200 a week to Brussels through the agency of the International Commission for Relief. Over £25,000 were disbursed in this manner, and the details of every grant and the destination of every cheque were scrutinised by Godlee, who was also a generous contributor in money.

After the war Godlee gradually passed more and more of his time at Coombe End Farm, a beautiful place, lying on the summit of Whitchurch Hill, above the Thames. Here he devoted his time, when official business did not bring him to London, to the farming of his property and the writing of the biography of Lister. The life of Lister appeared in 1917, and was written in the spirit dictated by its subject who had said "a scientist's public life lies in the work that is his." That is to say, the main part of the biography is a history of antiseptic surgery written by one who was intimately associated with Lister in his experimental work and its developments, and who for many years, in association with Sir Watson Cheyne, assisted him in his operative practice. We therefore find included in the book a graphic sketch of Victorian medicine in Edinburgh, Glasgow, and London, as well as on the continent, showing how the revolutionary doctrines were received, and the spirit in which they were interpreted. The biography met with the success which it deserved, went through more than one edition in this country, and is, we believe, in course of translation into German.

In private life this man of many posts and many honours was conspicuously simple, and save to his friends, a little austere. He was business-like and punctual, and got through much work, public and private, without haste or fuss. He was essentially accurate and inclined to be severe upon anything that savoured of pretence or pose. But he was the best of friends with those whose sincerity he recognised, and, whether in casual meeting or on more intimate occasions, could be an interesting and an amusing talker over a great choice of subjects. He was a linguist who had travelled considerably, he had a close acquaintance with many phases of art, and was himself a good water-colour painter. He had an unusual knowledge of botany and ornithology; he was a practical farmer and an assiduous gardener; and along the whole range of his accomplishments he was fully read and minutely documented. Latterly he lived almost entirely at his country house, where he died; and though his busy professional career had kept him all his life much in London, his joy in farming was of the sort that could only come from a real familiarity with the countryside. He loved the working of Nature.

Sir Rickman Godlee married in 1891 Juliet Mary, daughter of Frederic Seebohm, Lit.D., of the Hermitage, Hitchin, who survives him, and to whom the sympathies of all the medical profession will be extended in her loss. There were no children of the marriage.

The funeral took place on Thursday last at Whitchurch Hill, Oxon.

ROBERT JAMES McLEAN BUCHANAN,

M.D. Manch. and Liverp., F.R.C.P. Lond.

We regret to announce the death, on April 19th from pneumonia, of Dr. Robert J. M. Buchanan, professor of forensic medicine and toxicology at the University of Liverpool. Perhaps the career of Dr. Buchanan was in some respects unique, for he was justly proud of the fact that before he began the study of medicine he helped to build, as an apprentice joiner, the Liverpool Royal Infirmary, in which he later served as an honorary physician. Severing his apprenticeship with joinery as a young man, he began a distinguished career as a medical student at University College, Liverpool, gaining many class medals and later a Holt Fellowship in Physiology and Pathology, in which subjects he had acted as demonstrator. In 1888 he graduated M.B., Ch.B. with honours in systematic and clinical medicine, and obtained the M.R.C.S. Eng. In the same year he won the Derby Exhibition at Liverpool University in clinical medicine and surgery, and in 1889 he was awarded a gold medal by the Victoria University of Manchester for his M.D. thesis. In 1897 he became a Member of the Royal College of Physicians of London and a Fellow in 1908, having been awarded four years previously, in 1904, the M.D. Liverpool. Early in his career he became associated with the Department of Forensic Medicine and Toxicology at his University, and held therein successive appointments, culminating in the professorship, from which he retired at the end of 1924. His clinical experience as a physician was gained through his services to several Liverpool hospitals: first to the Stanley Hospital, then to the Hospital for Consumption and Diseases of the Chest, and finally as honorary physician to the Royal Infirmary, to the consultant staff of which he was appointed in June of last year. During the war he acted as captain in the R.A.M.C.(T.) and was one of the physicians of the First Western General Hospital. He was an active member of the Medico-Legal Society and the Liverpool Medical Institution. Some years ago the Southport Medical Society elected him as their president.

Dr. Buchanan's chief contributions to medical literature include a monograph on "Rabies and Hydrophobia," and the reissue of "Husband's Forensic Medicine," minus the public health section, as "A Text-book of Forensic Medicine and Toxicology," brought thoroughly up to date. In 1909 he published "The Blood in Health and Disease," a well-known and excellently illustrated manual. He was the author of several articles in the Practical Encyclopædia of Medicine and Surgery, among them "Diseases of the Pleura and Mediastinum" and "Diseases of the Spleen and Thymus." His judgment as a physician was highly valued by his colleagues, who recognised his worth as a sound, experienced, and reliable consultant. His book on diseases of the blood showed him an expert microscopist and an excellent draughtsman, as well as an apt microphotographer. He was a regular exhibitor of his own paintings and water-colour sketches at the autumn and other exhibitions in Liverpool—sketches more especially of the picturesque features of North Wales. Moreover, he was a keen disciple of Izaak Walton and had an intimate knowledge of the best trout streams around Liverpool. A man of singular versatility and abounding energy, he was a lover of music and a raconteur of the first order.

A colleague writes of him: "In Dr. Buchanan we have lost one of those all too rare ornaments of the profession who, in spite of the labours of the day and the demands of ever-advancing knowledge, are able, by their literary or artistic gifts, to lift the mind above common things and add to the sum of human happiness."

He lost his elder son, who had just begun to study medicine, about five years ago, a blow which left a deep impress on Dr. Buchanan's health. The sorrow of his widow and younger son will be shared by many thousands of his patients in and around Liverpool, who profited by his skill and ever-ready kindness in the wards and in private practice.

SAMUEL REGINALD ORME DUDFIELD,

O.B.E., M.B., D.P.H. Camb., M.R.C.S. Eng.

Dr. S. R. O. Dudfield, medical officer of health for Paddington, died on Sunday at the Hospital of St. John and St. Elizabeth, St. John's Wood, from appendicitis, at the age of 64. He was the son of Dr. T. Orme Dudfield, a former medical officer of health for Kensington. He went up to Trinity College, Cambridge, where he took his Natural Science

Tripos in 1882. He then studied medicine at St. Bartholomew's Hospital, London, and in 1885 qualified as L.R.C.P. Lond. and M.R.C.S. Eng., graduating two years later as M.B., C.M. Camb., and taking his D.P.H. in the following year. Dr. Dudfield's first public health appointments were as assistant medical officer to the Homerton Fever Hospital and medical officer of health for Eastbourne. For a period of over 30 years he acted as medical officer of health for Paddington, for a large part of which time he was editor of *Public Health*, the official publication of the Society of Medical Officers of Health. Dr. Dudfield had a mathematical mind which turned naturally to the statistical solution of public health problems. He was a severe critic of slipshod method and regarded the lack of exact definition of puerperal fever as invalidating the mortality returns from this disease, while championing the right of the practitioner often to be in honest doubt in the diagnosis of exanthemata. He took an active part in the proceedings of the Royal Statistical Society, of which he was Guy Medallist and to which he held the position of honorary foreign secretary, while he was a titular member of the International Statistical Institute. His contributions to the *Journal of the Statistical Society* include such articles as On the Critical Examination of Methods of Recording and Publishing Statistical Data bearing on Public Health: Suggestions for the Improvements of Such Methods (1905); Some Unconsidered Factors Affecting the Birth-rate (1908); Still-births and Infantile Mortality (1912); Life Tables for Infants: Methods of Construction (1911). Dr. Dudfield was also at one time President of the Harveian Society and honorary secretary of the Epidemiological Section of the Royal Society of Medicine. Under the old Volunteer regulations he held the rank of surgeon-lieutenant to the 26th Middlesex Cyclists' Corps of the Rifle Volunteers, and during the war he was captain in the R.A.M.C. (T.), attached to the 1st City of London Sanitary Company. For his services in the field he was mentioned in despatches and received the Order of the British Empire. His death is a distinct loss to the public health service.

THE LEGAL RESPONSIBILITY OF THE SURGEON.

A MEETING of the Medico-Legal Society took place in the rooms of the Medical Society of London on April 21st, Lord Justice Atkin, the President, occupying the chair.

Lord Riddell read a paper introducing a discussion on the legal responsibility of the surgeon. He said he had no desire to lay down legal or medical opinions, but to ventilate the matter and ask for a reconsideration of problems which had arisen in these changed times of aspiration and needs, or imagined needs. The rules laid down in regard to criminal responsibility could be shortly epitomised; everyone, whether a licensed practitioner or not, was protected from criminal responsibility for performing, with reasonable care and skill, any lawful surgical operation on a person with his consent and for his benefit, providing he had regard to the patient's state at the time and all the circumstances of the case. Consent could be given by guardians or relatives. That consent, however, must not be exceeded. Neither lawyers nor doctors guaranteed cures; they only contracted to do their best, and this meant that a higher degree of skill was to be expected from the specialist than in the case of the ordinary practitioner. "Lawful" and "for his benefit" were subject to different interpretations. Ethical questions arose when considering the degree of danger for what would be otherwise a criminal offence. If the mortality from a certain operation was 97 per cent., was the surgeon justified in operating, after explaining the circumstances to the patient? Should it be done to please the patient? Lord Riddell did not think rules could be laid down in this respect.

Sterilisation.

His main purpose was to draw attention to the situation in regard to sterilisation which had arisen out of the modern teaching in eugenics and the recent discoveries in medical science. Under what circumstances was it justifiable to render men or women sterile? The practitioner had a duty to the State as well as to the patient, and this view had always been insisted on by the State, both in the matter of sterilisation and maiming. No surgeon was bound to perform an operation for sterilisation, but could he do it by agreement with the patient or her relatives? And, if so, under what circumstances? It was frequently thought that, apart from legal abortion, a surgeon and patient could agree to an operation, and if death resulted the surgeon was relieved of responsibility. That, however, was wrong. A man and a woman were not held to be masters of their own bodies, to dispose of as they wished, and the prohibition of self-maiming arose out of the same principle. Baron Bailey expressed the principle by saying that a prosecution in such cases was for the public benefit, and the willingness of the patient could not take away the offence against the public. In early days castration seemed to have been a common offence by injured husbands and angry women, but afterwards it was treated as a felony and was punished by death, the original object of the punishment being that the act took away the person's courage. The punishment had become modified, but it was still an offence; castration, except for pathological reasons, was illegal, and the surgeon was then guilty of unlawfully wounding, whether it was done with consent or not. Vasectomy for the purpose of preventing offspring came into the same category.

Sterilisation of women was a more frequent operation than castration, and the questions involved were of wide and growing importance. The law was not so clear on the sterilisation of women as it was in regard to castration in men. In women the removal, with or without the consent of the person, of uterus, ovaries, or Fallopian tubes was illegal, and was held to be against public policy. If pregnancies in a particular woman had been shown to be both difficult and dangerous, was the surgeon justified in sterilising her to save her life? And was one rule to be applied to married women and another to unmarried? If a woman had five children in five years and was much reduced in health in consequence, did that justify sterilisation? His view was that each case must be treated on its individual merits. The question was a very large one, especially in view of the fact that in this kingdom a child was being born every two minutes, and birth control had changed the habits of 350 million people in Europe and America, where, in a general way, the birth-rate was falling, and this quiet revolution might spread to the East. The matter should not be left entirely in the hands of the professors of gynæcology; the public were entitled to know what were the opinions held by the medical profession on the subject. If a wife gave consent for her sterilisation and the husband's consent had not been asked, he might have a cause of action for being deprived of the possibility of offspring, but he would have no cause for action if the operation were rendered necessary by a definite pathological condition. Mentally defective women were prolific in the matter of children; was sterilisation a legal procedure in such cases? He considered that it was not, unless the operation were for the medical welfare of the patient. It was illegal when performed solely to prevent her from having children.

In conclusion, Lord Riddell raised the question of cosmetic operations such as those associated with beauty parlours, the operations for the dispersal of the double chins of middle-aged women, and so forth. If sepsis and death ensued, did a charge of manslaughter lie against the practitioner?

Discussion.

Sir William Willcox said the medical man did not do an operation because the patient wanted it; if that course were pursued, it would be bad for both patient and the medical man. There must be some real medical benefit aimed at by the operation. He agreed that the operation of vasectomy in order to prevent the bringing of children into the world was illegal, and the use of X rays for such purposes came into the same category. He was strongly against the sterilisation of mental defectives, especially as it was often difficult to say who were mentally defective.

Sir Charters Symonds said the public had a right to express an opinion on the subject of the sterilisation of mentally defective persons. While such people were kept under supervision in institutions they were industrious and harmless, but if they improved and were allowed out, the girls became prostitutes and the men trended towards crime. His own view was that the time had come when these people should be sterilised.

Prof. Louise McIlroy quoted the case of a working woman with an ovarian tumour which caused her great pain, and her husband, in consequence of a quarrel they had had, would not consent to the removal of the tumour. In consequence she had to leave the hospital again unrelieved. That raised the question whether, the woman having consented, the operation should be done. She, the speaker, did not think that problem would ever be cleared up. In some cases, in which the doing of an operation was a danger to the patient's life, it was necessary to hedge somewhat on the legal aspect, and decide on the general circumstances of the case. The possible death of the patient should not affect the question of the operation itself. Now that the dosage of X rays was a matter of more exactitude, sterilisation could be produced for a year, and at the end of that time renewed if necessary. But in regard to many of these cases of difficult decision she could not avoid the feeling that she was walking on a volcano all the time. She did not know whether, in any action brought in respect of such cases, the surgeon would have the support of the legal profession, but the heads of the surgical profession would probably back up the procedure. She felt very strongly that surgeons had no right to sterilise mental defectives; she regarded that as an assault. These people were better in institutions; if allowed to go out, they interfered with the morals of the community. Sterilisation because of syphilis should never be done, and that was not so necessary now as the disease was much more curable.

Dr. Douglas Cowburn said the surgeon was actuated by the one single motive, the good of the patient. He was not liable for an error of judgment, even though such error might cause the death of the patient, unless it was so gross as to be inconsistent with reasonable skill, care, and diligence. He proceeded to discuss the relative responsibility of the surgeon and the anæsthetist.

"VOYAGE D'ETUDES MÉDICALES."—The nineteenth Voyage d'Etudes Médicales to the health resorts of France (organised solely for the medical profession) will take place during the first part of September under the scientific direction of Profs. Carnot and Rathery and will be devoted to the resorts of the north and east. The party will assemble at Berck-sur-Mer and will first visit Paris-Plage, Lille, and Saint-Amand, and thence proceed to Belgium in order to visit Brussels, Spa, Luxembourg, and Mondorf. Returning to France, via Niederbronn and Morsbronn, the nineteenth V.E.M. will visit Strasbourg, proceeding from there by motor-car to Schirmeck, le Hohwald, Sainte-Odile, Chatenois, and Ribeauvillé, then Colmar, Soulzmatt, Soulzbach, Munster, les Trois Epis, le Linge, le Col de la Schlucht, and Gerardmer. Crossing the Vosges again it will then follow the road of the Cretes and visit Bussang, Luxeuil, Plombières, Bains-les-Bains, Bourbonne, Martigny, Contrexéville, and Vittel. First-class accommodation is arranged throughout the journey and at the hotels. Further particulars may be obtained from Madame Juppé-Blaise, delegate of the French Spas, Office Français du Tourisme, 56, Haymarket, London, S.W. 1.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Lt.-Comdrs. to be Surg. Cmdrs.: F. C. Wright, H. E. Y. White, D. P. H. Pearson, I. S. Gabe, and A. J. Tozer.

Surg. Capt. E. T. Meagher is placed on the Retd. List with rank of Surg. Rear-Admiral.

ROYAL ARMY MEDICAL CORPS.

ARMY DENTAL CORPS.

Lt. T. D. Corke to be Capt.

TERRITORIAL ARMY.

Col. F. Kelly, having attained the age limit, is retired and retains his rank.

Lt.-Col. R. M. Vick resigns his commn. and retains his rank with permission to wear the prescribed uniform.

Majs. (Prov.) J. S. Hudson and A. C. Court are confirmed in their rank.

Capts. A. Morris and R. O. Ward to be Majs. (Prov.).

Lt. G. V. Davies to be Capt.

INDIA AND THE INDIAN MEDICAL SERVICE.

Maj. W. O. Walker, officiating civil surgeon, has been transferred from Jalpaiguri to Darjeeling, vice Lt.-Col. Proctor, transferred, or until further orders. Military Assist. Surg. S. J. V. Fox, civil surgeon, has been transferred from Jessore to Jalpaiguri, vice Maj. W. O. Walker, transferred, or until further orders. Military Assist. Surg. H. A. Young has been appointed to act as a civil surgeon and has been posted to Rajshahi, vice Maj. F. G. Gow, tcansferred, or until further orders. Lt.-Col. D. McCay, professor of clinical medicine, Medical College, Calcutta, and second physician to the College Hospitals, has been allowed leave for one year and seven months. Maj. J. D. Sandes, officiating civil surgeon, Hooghly, to act as professor of clinical medicine, Medical College, Calcutta, and second physician to the College Hospitals, vice Lt.-Col. D. McCay, granted leave, or until further orders. Maj. C. A. Godson, police surgeon, Calcutta, has been appointed to be civil surgeon, Hooghly, vice Maj. J. D. Sandes, transferred, or until further orders. The services of Capt. G. H. Fraser have been placed temporarily at the disposal of the Government of Bihar and Orissa for employment as officiating superintendent, European Mental Hospital, Ranchi. The services of Capt. N. Briggs have been placed temporarily at the disposal of the Government of the Punjab for employment in the Jail Department. Capt. A. C. Craighead has been appointed temporarily to the Medical Research Department, and posted as a supernumerary officer at the Central Research Institute, Kasauli, with effect from the date he takes over charge. The services of Lt.-Col. H. G. Stiles-Webb have been placed temporarily at the disposal of the Government of the Central Provinces. Col. J. A. Black, Inspector-General of Civil Hospitals, C.P., has been granted leave for a period of eight months. Col. F. Wall and Lt.-Col. H. Emslie-Smith have retired from the service. Capt. C. H. N. Baker has been appointed officer-in-charge, Medical Store Depôt, Rangoon, in addition to his other military duties.

DEATHS IN THE SERVICES.

Brigade Surg. Lt.-Col. William Edmondson Dudley, retd., who died at his residence in Bath at the age of 86 on April 13th, was born at Templemore, Tipperary, in 1838. He received his medical education at the Royal College of Surgeons in Ireland and qualified with the licentiateship of that body and with the L.A.H. Dub. in 1862. In the following year he obtained the L.R.C.P. Edin., and was appointed assistant surgeon to the 76th Regiment. From 1868 to 1871 he was on the Army Medical Staff and was afterwards attached to the Royal Artillery. Later he was attached to the 3rd Regiment (the Buffs) in the Zulu War of 1879 and was awarded the medal and clasp. In the Afghan War of 1880–81 he served with the 78th Highlanders. He retired in 1884 with the rank of hon. brigade surgeon.

The Minto Gold Medal for Research in Tropical Medicine for 1924 has been awarded to Maj. R. N. Chopra, I.M.S., of the School of Tropical Hygiene, Calcutta. This is the first time a member of the staff of the school has been the recipient of the award.

Medical News.

UNIVERSITY OF CAMBRIDGE.—At the examination for the Diplomas in Public Health, Hygiene, and Tropical Medicine and Hygiene (New Regulations) the following candidates were successful :—

Part I.—Mohammed A. E. M. El Diwany, Andrew N. Fergus, Abdel R. Hassan, Mary K. Henegan, Charles F. Pedley, Colin H. H. Robertson, Lalib Shehata, Charles J. Stocker (distinguished), William J. Vickers, Alan D. Whitelaw, and Man K. Yue.

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH, ROYAL COLLEGE OF SURGEONS OF EDINBURGH, AND ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.—At examinations held recently, of 125 candidates entered, the following 39 passed the Final Examinations :—

Henry Goldsmith, John A. Hyde, Lim K. Htoe, James Kirkness, Soo W. Tay, John Karkness, Fraser D. Muller, Harold B. Wainer, Robert T. Johnson, Winifred G. Price, Mohammed M. El-Makkawi, Alexander B. Jayasuriya, Appu H. T. de Silva, James L. Malone, Andrew Wilson, Myles E. T. Burke, Herbert A. Dirckze, Sayed Ghaleb, Arumugam Chellappa, William A. Kemp, Sundaramier Ramakrishnan, Moses Kopelowitz, Arthur F. Senewiratne, Joseph F. Hedley, William J. Ledgerwood, Ronald H. Mackintosh, James Houston, Douglas B. Craig, Sing K. Sie, Matthew L. Hendrie, John M. Coutts, Isaac Joels, Hapuarachige D. J. Lazarus, Mordchel Gordon, Owen L. F. Senaratne, Peter King, William M. F. Ker, Mohammad J. Quaraishi, and Arthur A. F. Shepherd.

Medicine.—Constance C. Reid, Ella D. Messenger, John J. McKenna, Constance P. H. Hunter, Byerley C. F. Leembruggen, Palhalli R. S. Rao, Ee K. Lee, Parimal C. Sen, Thomas W. Chapman, John R. Hetherington, and Benjamin A. Meyer.

Surgery.—Irma E. L. Mackenzie, Constance C. Reid, Frederick Blacklee, Ella D. Messenger, Boo E. Khoo, William A. F. Hurst, Mela R. Soni, Alexander S. Ballantine, and William T. Baker.

Midwifery.—Bailey G. V. Dias, Lionel H. Wilson, Frederick Blacklee, Ella D. Messenger, George R. Mitchell, John J. McKenna, Constance P. H. Hunter, William A. N. Chanmugam, Byerley C. F. Leembruggen, Arumugam W. Rosiah, Ursula van Rooyen, Palhalli R. S. Rao, James C. Stenhouse, Mary A. McGill, Ee K. Lee, Parimal C. Sen, Thomas W. Chapman, John T. Fernandez, Benjamin A. Meyer, Max Camrass, Archie Franklin, and Alfred S. Hunt.

Medical Jurisprudence.—James Sharpe, Robert W. Schuch, James Cook, Lionel H. Wilson, Cyril A. Munro, Set C. Chee, Edwin H. Eastcott, John L. I. D'Silveira, Mikhail Youakim, Emile Fischbacher, Chin E. Toh, John D. Cooper, David D. Radford, Theodore Lipschitz, Mary D. Clark, John B. Panton, Nathanael J. Knoesen, and George R. Mitchell.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION.—Beginning on Monday, May 11th, is a three weeks' course in Diseases of the Nose, Throat and Ear at the Central London Throat, Nose, and Ear Hospital, consisting of clinical demonstrations on out-patients and in the wards, lectures, &c., and an operative surgery class will also be available.—At the Maudsley Hospital a month's course in Psychological Medicine will be held from May 4th to 28th. The course will include lectures and demonstrations on the different aspects of mental disease. Various forms of clinical instruction will be open to those attending the course.—A two weeks' special course in Diseases of Infants will be given at the Infants Hospital from May 18th to 30th. The comprehensive syllabus covers clinical demonstrations, "round table" consultations, lectures, and four visits to centres away from the hospital.—An afternoon course in Dermatology will take place at the Hospital for Diseases of the Skin (Blackfriars) from May 18th to 30th. The work will embrace instruction in the out-patient department and the venereal clinics.—For those in general practice it is proposed to hold a two weeks' course at the London Temperance Hospital from May 18th to Friday, the 29th, Saturday excepted. The course will begin at 4.30 P.M., and will consist of a clinical demonstration (with cases) lasting for one hour, followed by a short lecture at 5.30 P.M. Programmes of the special courses for May can be obtained from the Secretary of the Fellowship at 1, Wimpole-street, London, W.

MAUDSLEY HOSPITAL.—A series of six clinical demonstrations of Types of Mental Disease will be given at the Maudsley Hospital, Denmark Hill, London, S.E., by Dr. Edward Mapother, medical superintendent, on successive Wednesdays, commencing May 6th, at 2.30 P.M. The series will be illustrated by numerous cases. Fee for the series 1 guinea.

NAVAL MEDICAL COMPASSIONATE FUND.—At the quarterly meeting of the directors of this Fund, held on April 17th at the Admiralty, London, S.W., Surgeon Vice-Admiral Joseph Chambers, C.B., C.M.G., Medical Director-General of the Navy, in the chair, the sum of £125 was distributed among the several applicants.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, April 27th.

ODONTOLOGY : at 8 P.M.

Clinical Evening :

Fellows and Members who are willing to show cases of interest are asked to communicate with the Hon. Secretary (Mr. Bayford Underwood, 26, Wimpole-street, W.) as soon as possible.

Tuesday, April 28th.

MEDICINE : at 5.30 P.M.

Papers :

Prof. Dr. E. Leschke (Berlin): Metabolism and the Sympathetic System.

Dr. O. Leyton : Hypoglycopyresis.

DISEASE IN CHILDREN
NEUROLOGY
THERAPEUTICS AND PHARMACOLOGY
} Members of these Sections are special invited to this meeting.

Friday, May 1st.

LARYNGOLOGY : at 5 P.M. (Cases at 4 P.M.)

Annual General Meeting :

Election of Officers and Council.

Cases and Specimens :

Shown by Mr. C. A. S. Ridout, Dr. Dan McKenzie, Sir James Dundas-Grant, Mr. G. W. Badgerow, Mr. H. A. Kisch, Mr. Walter G. Howarth, Mr. E. Musgrave Woodman, Dr. P. Watson-Williams, and others.

Dinner :

A combined dinner of the Sections of Laryngology and Otology will be held at the Langham Hotel on Friday, May 1st, at 7.30 for 8 P.M.

ANÆSTHETICS : at 8.30 P.M.

Annual General Meeting :

Election of Officers and Council.

Paper :

Dr. J. Blomfield : Accidental Damage during Anæsthesia.

Saturday, May 2nd.

OTOLOGY : at 10.30 A.M. (Cases at 9.45 A.M.)

Annual General Meeting :

Election of Officers and Council.

Paper :

Mr. Arthur Cheatle : The Mastoid Emissary Vein and its Surgical Importance (with specimens and lantern slides).

Specimens and Cases :

Shown by Mr. Arthur Cheatle, Mr. V. E. Negus, Dr. Dan McKenzie, Mr. Archer Ryland, and others.

ROYAL INSTITUTION, Albemarle-street, W.

TUESDAY, April 28th.—5.15 P.M., Prof. J. Barcroft : Effects of Climate on the Circulation (II.).

THURSDAY.—5.15 P.M., Mr. F. Kingdon Ward : Plant Hunting on the Roof of the World.

FRIDAY, May 1st.—5 P.M., Annual Meeting. 9 P.M., Prof. W. L. Bragg : Crystalline Structure of Inorganic Salts.

SATURDAY.—3 P.M., Mr. W. P. Pycraft : Use and Disuse—Effect of Structure on Animals (II.).

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

WEDNESDAY, April 29th.—8 P.M., Dr. Andrew Balfour : The Trend of Modern Hygiene.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith, W.

MONDAY, April 27th.—11 A.M., Surgical Registrar : Surgical Wards. 12 noon, Mr. Simmonds : Applied Anatomy. 2 P.M., Mr. Addison : Surgical Wards.

TUESDAY.—10 A.M., Medical Registrar : Clinical Methods. 12 noon, Dr. Burrell : Chest Cases. 2 P.M., Mr. Banks-Davis : Throat, Nose, and Ear Dept.

WEDNESDAY.—2 P.M., Dr. Burnford : Medical Wards. 2 P.M., Dr. Owen : Medical Out-patients. 2.30 P.M., Mr. Donald Armour : Surgical Wards.

THURSDAY.—10 A.M., Dr. Grainger Stewart : Neurological Dept. 11 A.M., Sir Henry Simson : Gynæcological Wards. 2 P.M., Mr. MacDonald : Genito-Urinary Dept.

FRIDAY.—11 A.M., Dr. McDougal : Electrical Dept. 12 noon, Surgical Registrar : Surgical Pathology. 2 P.M., Mr. Sinclair : Surgical Out-patients.

SATURDAY.—10 A.M., Dr. Saunders : Medical Diseases of Children. 10 A.M., Mr. Banks-Davis : Operations on Throat, Nose, and Ear.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Departments.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, April 27th, to SATURDAY, May 2nd.—HAMPSTEAD GENERAL HOSPITAL, Haverstock-hill, N.W. Special Post-Graduate Course in General Medicine and Surgery. Lectures and demonstrations daily (second week).—QUEEN'S HOSPITAL FOR CHILDREN, Hackney-road, Bethnal Green, E. Post-Graduate Course in Diseases of Children. Lectures and demonstrations morning and afternoon (second week).—ST. MARK'S HOSPITAL FOR DISEASES OF THE RECTUM, City-road, E.C. Post-Graduate Course in Proctology. Lectures, demonstrations, and operations every afternoon (second week).

UNIVERSITY COLLEGE HOSPITAL.

FRIDAY, May 1st.—11 A.M., Prof. A. V. Hill: The Physiology of Muscle and Nerve. (First of four public lectures.)

UNIVERSITY OF LIVERPOOL POST-GRADUATE LECTURES. (At 3.30 P.M.)

TUESDAY, April 28th.—(At the Royal Southern Hospital.) Dr. F. H. Barendt: Common Skin Infections in Childhood.

WEDNESDAY.—(At the Northern Hospital.) Mr. T. P. McMurray: Arthrites of the Hip.

THURSDAY.—(At the Stanley Hospital.) Miss Nicholson: Ovarian Tumours.

FRIDAY, May 1st.—(At the Royal Infirmary.) Dr. Henry Cohen: Recent Therapeutic Advances.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, April 28th.—4.15 P.M., Mr. D. L. Sewell: Empyema of the Maxillary Antrum.

FRIDAY, May 1st.—4.15 P.M., Dr. F. Craven Moore and Mr. J. Morley: Demonstration of Cases.

MANCHESTER BABIES' HOSPITAL, Burnage-lane, Levershulme.

FRIDAY, May 1st.—8 P.M. (Post-Graduate Lecture), Mr. George Graham: The Use of Insulin for Young Children.

Appointments.

ASH, W. M., M.B., B.S. Lond., F.R.C.S. Edin., has been appointed Medical Officer of Health for Derbyshire.

BARR, W., M.B., Ch.B. Glasg., D.Sc. (P.H.), Medical Officer of Health for Rotherham.

BRUNTON, C. E., M.B., B.Ch. Dub. , Research Pathologist to the Christie Hospital, Manchester.

DAVIES, G. I., L.R.C.P. Lond., M.R.C.S., Assistant Medical Officer, Lewisham Hospital.

HUGHES, E. R., L.R.C.P. Lond, M.R.C.S., Medical Officer and Public Vaccinator for the Holyhead District.

MCCULLAGH, W. MCK., F.R.C.S. Eng., M.B., B.Ch. Belf., Assistant Surgeon to the Samaritan Free Hospital for Women, Marylebone-road.

RENNET, M. J., M.B., Ch.B. Aberd., Assistant Medical Officer of Health, Chester.

TAYLOR, J. S., M.B., Ch.B. Aberd., Senior Resident Medical Officer, Aberdeen City Fever Hospital,and Assistant Medical Officer of Health.

TIBBLES, SYDNEY, L.R.C.P. & S. Edin., Honorary Ophthalmic Surgeon to St. Pancras Dispensary.

Vacancies.

For further information refer to the advertisement columns.

Barnet, Wellhouse Hospital.—Res. M.O. £350.

Birmingham, Dudley-road Hospital.—Sen. Res. Surg. O. £700.

Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.

Bradford Royal Infirmary.—Two H.S.'s. Each £150.

Bristol, Royal Hospital for Sick Children and Women.—H.S. £125.

Cairo School of Medicine.—Asst. Prof. of Chemistry. L.E.720.

Cambridgeshire Tuberculosis Colony.—Asst. M.O. £300. Also H.P. at rate of £100.

Carmarthen, Joint Counties Mental Hospital.—Asst. M.O. at rate of £350.

City of London Hospital for Diseases of the Heart, &c., Victoria Park, E.—H.P. at rate of £100.

Dublin, Dept. of Local Government and Public Health.—Travelling Fellowships.

Durban Corporation, Natal.—Asst. M.O.H. at rate of £900.

Eastbourne, Princess Alice Hospital.—Res. H.S. at rate of £175.

East Ham County Borough.—Asst. M.O. £600.

Harefield, Middlesex, County Tuberculosis Sanatorium.—Third Asst. Res. M.O. £400.

Holland County Council, Lincolnshire.—Asst. County M.O. £600.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Hon. Asst. P.

King's College Hospital, Denmark Hill, S.E.—Hon. Psychotherapist.

Liverpool, New Psycho-Therapeutic Clinic.—Hon. Asst. P.

London County Council Mental Hospitals.—Eighth Asst. M.O. £440.

London Lock Hospital, 91, Dean-street, W.—Temp. Hon. S. to Out-patients.

Mexborough, Montagu Hospital.—Hon. Visiting and Consulting Surgeons.

Nottingham General Dispensary.—Res. Surg. £200.

Plymouth County Borough.—Asst. M.O.H. £750.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Asst. S.

Rochford Hospital.—Asst. Res. M.O. £125.

Royal Free Hospital, Gray's Inn-road, W.C.—Third H.S.

Royal Society of Medicine, 1, Wimpole-street, W.—Secretary. £800.

Ruthin Castle (Duff House), North Wales.—Jun. Res. P. £150.

St. Mary's Hospital for Women and Children, Plaistow, E.—Res. M.O. and Asst. Res. M.O. at rate of £175 and £130 respectively.

St. Pancras Hospital, Pancras-road, N.W.—Med. Supt, &c. £700.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—Reg. at rate of £100.

Southampton, Free Eye Hospital.—H.S. £150.

Stoke-on-Trent County Borough.—Asst. M.O. £500.

Westmorland Sanatorium, Meathop, Grange-over-Sands.—Res. Asst. M.O. £350.

Whittingham County Mental Hospital, Preston, Lancs.—Two Temp. M.O.'s. Each £7 7s. weekly.

Winsley Sanatorium, near Bath.—Asst. Res. M.O. £250.

Wolverhampton and Staffordshire Hospital.—H.S. at rate of £150.

THE Chief Inspector of Factories, Home Office, London. S.W., announces the following vacant appointments:—Lyndhurst, Hants; and Calvert, Bucks.

Births, Marriages, and Deaths.

BIRTHS.

BROUGHTON-ALCOCK.—On April 12th, at Grosvenor-street, W., the wife of Dr. W. Broughton-Alcock, of a daughter.

CLEMENTS.—On April 9th, the wife of Dr. W. A. Clements, of Daventry, Northants, of a daughter.

EVANS.—On March 26th, at Aden, Arabia, to Marjorie, the wife of Captain R. R. Evans, R.A.M.C.—a daughter.

GOODWIN.—On April 14th, at Acacia-road, St. John's Wood, N.W., the wife of Aubrey Goodwin, F.R.C.S., of a daughter.

HIGSON.—On April 12th, at a London nursing home, the wife of Dr. W. Davies Higson, "Eversley," Boxley-road, Maidstone, of a daughter.

MCCORMICK.—On April 14th, at St. John's Wood-court, N.W., the wife of Dr. J. E. McCormick, of a daughter.

MARRIAGES.

OLIVER—BARRITT.—On April 16th, at Albert-road Wesleyan Church, Colne, Thomas Herbert Oliver, M.D., to Martha Florence Barritt, M.B., Ch.B., younger daughter of Mr. and Mrs. D. H. Barritt, of "Brantwood," Colne.

SYMONS—DE WILDE.—On April 18th, at the Church of St. Martin-in-the-Fields, London, Hubert Wallace Symons, M.B., F.R.C.S., Major, R.A.M.C. (T.A.), to Charlotta Dolores Naomi de Wilde, M.R.C.S., L.R.C.P., younger daughter of the late Mr. and Mrs. Henri de Wilde, of Utrecht and London.

DEATHS.

DUDFIELD.—On April 19th, from appendicitis, in London, Samuel Reginald Orme Dudfield, O.B.E. (Mil.), late Captain R.A.M.C., M.A., M.B., D.P.H., F.S.S., M.O.H. for Paddington for 30 years, aged 64.

DUDLEY.—On April 13th, at Portland-place, Bath, Brigade Surgeon Lieut.-Colonel William Edmondson Dudley, aged 86.

ELLIOTT.—On April 18th, after a short illness, Thomas Elliott, M.D., of Church-road, Tunbridge Wells, aged 75.

GODLEE.—On April 20th, at Coombe End, Whitchurch, Oxon, after a few hours' illness, Sir Rickman John Godlee, Bt., K.C.V.O., F.R.C.S., aged 76.

LIBBY.—On April 18th, at Rudyard, Staffordshire, Harold Samuel Libby, L.R.C.P., M.R.C.S.

RAYNE.—On April 17th, at St. Mary's Gate, Lancaster, Charles Alfred Rayne, M.D., aged 79.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

THE LANCET: SUBSCRIPTION RATES.

INLAND	One Year	£2	2	0
	Six Months	1	1	0
	Three Months	0	10	6
ABROAD	One Year	2	10	0

Subscriptions not paid in advance are charged out at the published price of 1s. per copy, plus postage. Cheques and P.O.'s (crossed "Westminster Bank, Ltd., Covent Garden Branch") should be made payable to THE MANAGER, THE LANCET Offices, 423, Strand, London, W.C. 2.

REMOVAL OF BETHLEM HOSPITAL. — Formal notification is made of the intention of the City corporation and the governor of Bethlem Hospital to apply to Parliament in the present session for an Act to empower the transfer and purchase of property necessary for the removal of the institution to Monks Orchard Estate at Beckenham and West Wickham, in Kent.

Notes, Comments, and Abstracts.

HEALTH CONDITIONS IN THE FEDERATED MALAY STATES.

Mr. William George Maxwell, C.M.G., Chief Secretary to Government, is responsible for the annual report, on which the following summary is based. The Federation comprises four States: Perak, Selangor, Negri Sembilan, and Pahang. A census taken in April, 1921, showed that the population was then 1,324,890, having increased since 1911 by 27·7 per cent. Of this population 853,528 were males and 471,362 females. The Malay population was 510,821, and the Chinese population 494,548, whilst 305,219 persons of Indian nationality were enumerated, more than four-fifths of these being Tamils. The European population rose from 3284 in 1911 to 5686 in 1921, of whom 92·3 per cent. are of British origin. The most satisfactory feature of the census is that all the statistics, of sex, of marriage, of age, and of birthplace, show that the immigrant races, who have done so much to develop the resources of the Federated States, are ceasing to look upon these States as a place of temporary sojourn, and are tending more and more to make their permanent home here. The birth-rate in 1923 was 25·66 and the death-rate 24·40 per mille. There were 6420 deaths of children under 1 year of age, being an infantile mortality of 180·07 per mille.

Causes of Sickness and Death.

As usual, malaria heads the list as the most important cause of sickness and deaths. The number of deaths recorded was 15,516 (11·17 per mille). Considerable attention is being focused on the educational side of the malaria problem and the arousing of public interest therein. Malaria is a notifiable disease in many sanitary board areas. Difficulty continues to be experienced in inducing the public to avail itself of the facility for hospital treatment of venereal diseases in the early stages. Public education regarding these diseases is, however, being actively promoted. Venereal disease clinics, centres, and propaganda are in process of organisation. Injections of novarsenobenzol were given in 29,675 cases. The campaign against yaws was continued throughout the year with gratifying results. Injections of novarsenobenzol were given to 31,135 persons, as against 22,972 in 1922. Little trouble is found in persuading people to undergo treatment, and considerable progress has been made in the eradication of this disease. Sixteen cases of plague, 12 of cerebro-spinal meningitis, 32 of small-pox, and 17 of diphtheria occurred. There was no case of cholera.

Infant Welfare.

The infant welfare centre in Kuala Lumpur has made extraordinary progress. The centre is primarily an educational institution, which provides for young mothers of all nationalities advice and teaching in the care and management of their infants. The work of the centre is directed rather to the supervision of the health of the infant and the education of the mother than to the treatment of the sick, but the incidental treatment of simple ailments is nevertheless included within its scope. The staff consists of a lady medical officer, a European nursing sister, and six health visitors. "Health visiting" is an essential factor in the programme of the infant welfare, and it is satisfactory to record that the prejudice against the invasion of the home by strangers, which is even more marked in the East than in the West, is gradually disappearing as the mothers are understanding that the object of the visit is to help and not to harass. Particular attention is given to ante-natal work, and to education and propaganda. The Kuala Lumpur centre has been so successful that arrangements are being made to extend this form of activity to other places.

Hospitals and Dispensaries.

There are in the Federated States 4 European hospitals, 40 district hospitals, 3 women's hospitals, 3 leper asylums, 7 gaol hospitals, 1 quarantine camp (for immigrants), 4 vagrant or decrepit wards, 1 mental hospital, 14 out-door dispensaries, and 10 town dispensaries. During the year there were 87,310 indoor patients. Outdoor patients numbered 527,414, as compared with 433,111 in 1922 and 329,310 in 1921; the increase is due in a great measure to the travelling dispensaries which were started towards the end of 1922. These bring medical requirements to sufferers living in distant places removed from ordinary medical facilities. On Dec. 31st the patients at the only institution for mental disorders—the Central Mental Hospital, Tanjong Rambutan—numbered 900 males and 254 females. During the year 358 men and 111 women were admitted. The increase in the number of female admissions is noteworthy; alcohol accounted for 42, and syphilis for 25 admissions. The commonest form of mental disease on admission was recent melancholia, with 115 victims.

In the department of research the investigation into the disease meliodosis was continued throughout the year, and additional evidence obtained in demonstration of its specific character. The first recorded case of the disease in a European came under observation. A rare case of typhoid septicæmia was discovered and examined. The Far Eastern Association of Tropical Medicine at the Fifth Congress held in Singapore in September discussed at length the subject of beri-beri, and finally adopted a number of resolutions, including a recommendation that each of the Governments interested and the International Health Board of the Rockefeller Foundation be invited to nominate a representative on a beri-beri committee which shall report at the next Congress. Investigations were conducted in connexion with cases of plague which occurred in Kuala Lumpur during the months of April and May. Live rats examined showed a flea index of 3·0, and all fleas were of the species *Xenopsylla cheopis.* These results dispose of the surmise that freedom from serious outbreaks of plague in this country might be due to the absence of an efficient transmitting agent. Further valuable research into the treatment of malaria by quinine and other alkaloids of cinchona has been conducted.

Research into the subject of the seasonal prevalence of species of anopheline mosquitoes was continued. As a result of investigation covering a period of three years, the definite conclusion appears to emerge that these mosquitoes occurring in this country have no definite breeding season, but breed throughout the year, and increase in frequency when conditions become suitable. Investigation work was undertaken on estates in Johore and at Sabak Bernam. At the latter place five specimens of *A. barbirostris*, a species hitherto considered to be innocuous, were found to be infected, and there appears little doubt that the species is an important factor in the outbreak of malaria there.

Temperature and Rainfall.

The temperature of the west coast of the Malay Peninsula has but a small daily range and little appreciable variation. On the east coast, however, the north-east monsoon, lasting from November to March, causes a distinct meteorological contrast with the rest of the year as regards wind and rainfall. Records from typical stations on the west of the peninsula, where the south-west monsoon is broken by Sumatra, show a decrease of rainfall from May to August. At Kuala Lipis, on the east of the main range, there is a general rise in rainfall from February until May, succeeded in some years by a distinct drop in July and August; there is a further rise culminating in October and November, followed by a fall to moderate rainfall in December and January. Charts, however, cannot bring out two points: the brilliant sunshine, which is the rule during the morning, and the dry spells of a fortnight or more when the grass becomes parched. In the mountains the rainfall is very high, the yearly average at Maxwell's Hill above Taiping from 1912–19 being 258 inches. At Telebu in Negri Sembilan, the driest station where records were kept, the average for 1905–19 was 60 inches. The heat, owing to the moisture of the atmosphere, is at times oppressive, although 100° F. has never been recorded in the shade.

DETERMINATION OF THE TOTAL MASS OF THE BLOOD.

IN a recent issue of the *Archives de Cardiologia y Hematologia* (vol. iii., March, 1924), of which we have received a reprint, Drs. F. Sanchis Perpina and R. Diaz Sarasola describe a method of determining the total mass of the blood, which is a modification of that employed originally by Harris and Loewy in America as follows: (1) They first determine the relative amounts of serum and blood corpuscles by centrifugalising in a graduated tube 10 c.cm. of the blood; (2) they inject intravenously 1 c.cm. of a watery solution of Congo-red which has been determined colorimetrically; (3) after five minutes another 10 c.cm. of the blood is taken and centrifuged. and the serum is then compared in Hellige's colorimeter with a 1 per cent. solution of Congo-red in serum. They give a table of equivalents between the colorimeter scale and the total quantity of serum, which presumably has been arrived at by adding a 1 per cent. solution of Congo-red to a known quantity of serum and from this they calculate the amount of serum adding in the corpuscles. The table gives up to 600 c.cm., which has been sufficient for their experiments on the dog. The authors admit that the method is not very exact, putting the limit of possible error at 6 per cent., as verified by animal experiment so far as possible. If the scale is prepared as suggested, the question may be asked: Is the Congo-red solution taken up by blood in vitro in the same proportion as when it is circulating in the tissues?

"GERM DISSEMINATION."

A MEDICAL man writes to us, under this title, drawing attention to the complete recklessness not only of the public but of individuals who from their position should know better, as to the possible spread of infections from the coughing, sneezing, and nose-blowing performances of the victims of catarrh. Our correspondent is himself a pulmonary subject who, as he says, "personally coughed and sneezed my way through life," and he has found it practicable through the use of relays of paper handkerchiefs and an invariable watchfulness to secure the public as well as the members of his family from the chances of infection due to carelessness. As an example of such carelessness he says: "Behold no less a personage than the M.O.H. of my borough, who at great length and with great particularity erroneously diagnoses his complaint as recurrent disease of the antrum, coughing and sneezing to the peril of anyone within the range of ten yards, and emphasising his sufferings and rounding his periods with an oratorical flourish of the handkerchief." His visit was followed by an outbreak of influenzal colds.

By a coincidence the situation is the subject of the illustration which follows, reproduced from the April *Bulletin of the City of Chicago Municipal Tuberculosis Sanitarium.*

KA CHOO!!
KA CHOO!!

The legend beneath is :—

"This is the man with the cold,
He shares his germs with neighbours and friends,
And keeps the children from growing old."

The picture is one that we have all seen in our own trains, as well as in buses and theatres, well-educated citizens appearing to believe that if they conform to the printed regulation against spitting—and save in the lowest classes the habit has largely disappeared as an ordinary conformity to manners—they have taken all the precautions required of them against the spread of infection.

"NURSING DON'TS."

AT the fifteenth annual Hospital, Nursing, and Midwifery Exhibition and Conference, which is being held this week at the Central Hall, Westminster, Dr. George Steele-Perkins delivered on Monday, April 20th, an address to nurses, in which he gave his hearers the crystallised fruits of much practical experience in the little details that make for the comfort of the sick. The lecture was entitled "Nursing Don'ts," and the speaker hoped that by setting red lights at the pitfalls of nursing, the right road might more easily be followed. Out of the wide range of subjects covered, we might with profit reproduce a few of Dr. Steele-Perkins's wise utterances, chosen at random. He says to nurses :—

Don't knock against a bed—to do so is very painful to gouty and rheumatic patients, and to patients in pain—it is very unpleasant to *all* patients and shows you are careless, and hence a patient may lose confidence in you.

Don't be high and mighty—study the convenience of the people with whom you are, while also maintaining your professional dignity.

Don't tell stories to endeavour to show the skill of your pet doctor.

Don't stay in the sick room *all* the time of the doctor's visit. It is tactful and thoughtful to retire, so that a patient can have the opportunity of making any complaint should he wish to do so, and which he might not care to make before the nurse.

Don't say "Dear" to any female patients over 18—they do not like it.

Don't neglect to cleanse your thermometer in the presence of your patient—patients can't help the thought "into whose mouth did that thermometer go last, and I wonder if it has been cleaned since ?"

Don't be harsh on a patient's relatives. They may have no medical knowledge, but they are naturally anxious and worried. They mean well, even if they are sometimes fussy.

Don't expect the relatives in a private house to be invisible, as in hospital, only existing, as it were, between three and four on visiting days.

Mutatis mutandis, others besides nurses might do well to remember a few of these points.

THE CURE OF PRESENT DISCONTENTS.

AN anonymous writer in the *Bath Herald*, stimulated by the Prime Minister's recent plea for a spirit of goodwill and coöperation among all parties, pointed out recently that one relief for our present disabilities would be for each one to disallow in himself or herself the desire for more money to expend on objects wrong in themselves or in excess. This is topical counsel for the season we have just passed, and sound advice at all times. The writer enters a plea for economy and the banishment of luxury, two things which must escape exact definition, as both are conditioned by circumstances. Rightly interpreted, however, and exercised, these virtues would promote the health and well-being of the community to an amazing extent. Some of the illustrations which the writer gives in proof of the lack of these virtues among the community are very familiar but none the less forcible. Obvious waste of food is a social crime, but money spent reasonably on entertainment improves the work done ; such expenditure becomes unreasonable only when the output or standard of work suffers through excess of amusement. Betting by introducing an element of complete chance into domestic budgets must always be uneconomical, while the writer would find large endorsement to-day of his view that wines and spirits should be used as medicines rather than daily beverages.

WIRELESS IN HOSPITALS.

THE use of broadcast receivers in hospitals and kindred institutions has stimulated Messrs. A. J. Stevens and Co., Ltd., of Walsall-street, Wolverhampton, to construct a radio-receiving set particularly adapted for institutional use. As shown by the illustration, it consists of a specially designed cabinet containing a new model four-valve set which can be used on a frame or indoor aerial, and with plug-in coils is capable of responding to all wave-lengths from 150 to 20,000 metres. With a good aerial and earth equipment it is claimed that several loud speakers can be worked from the one instrument. It is pointed out that the special method of low-frequency intervalve coupling employed almost completely eliminates undesirable outside interference, thus enhancing the quality of music and speech received. The containing cabinet is fitted with rubber casters to ensure silence in moving the set, and receptacles are provided to contain spare head-phones, the cupboards for the batteries being fitted with lock and key. The price of this hospital set is £47 plus the Marconi royalty of £2 10s.

—MIDDLESEX HOSPITAL JOURNAL.

Demy 8vo. Pp. xvi. + 1734. With 810 Illustrations, plain and in colour. Price **35s.**, postage 1s.

FIFTH EDITION. Demy 8vo. Pp. xx + 1023. With 55 Illustrations. Price **25s.**, postage 1s.

MONRO'S MANUAL OF MEDICINE

"*Among the standard text-books of medicine in the English language Professor T. K. Monro's Manual, now in its fifth edition and in its twenty-second year, has a deservedly established position as a clear and thoroughly sound book.*"
—BRITISH MEDICAL JOURNAL.

"*The best text-book of surgery in English.*"—LANCET.

ROSE & CARLESS' SURGERY

ELEVENTH EDITION. Demy 8vo. Pp. x + 1600. With 17 Coloured Plates, an X-ray Supplement, and 634 other Illustrations. Price **30s.**, postage 1s.

FOURTH EDITION. Pp. xvi + 441. With 298 Illustrations. Price **15s.**, postage 9d.

WHEELER'S OPERATIVE SURGERY

"*It is a thoroughly sound practical book, in which the most important points of all the ordinary operations are put forward in a clear and concise manner.*"—BRITISH JOURNAL OF SURGERY.

FIFTH EDITION. Demy 8vo. Pp. x + 242. With 42 Illustrations. Price **10s. 6d.** net, postage 9d.

SQUINT: Its Causes, Pathology and Treatment

By **CLAUD WORTH,** F.R.C.S. Eng., Consulting Surgeon, Royal London Ophthalmic Hospital.

"*Mr. Worth's treatise is original, full of ideas, and rich in useful diagnostic and therapeutic points. We think that every ophthalmic surgeon ought to read it.*"—ARCHIVES OF OPHTHALMOLOGY.

SECOND EDITION. Demy 8vo. Pp. xii + 288. Price **7s. 6d.**, postage 6d.

DOMICILIARY TREATMENT of PULMONARY TUBERCULOSIS

By **F. RUFENACHT WALTERS,** M.D., B.S., F.R.C.S. Eng., Medical Director, Crooksbury Sanatorium.

"*To all who are responsible for or interested in the treatment of cases of pulmonary tuberculosis, Dr. Walters' handbook will prove of practical value as a book of reference, and particularly by reason of the detailed and reliable information it contains.*"—BRITISH JOURNAL OF TUBERCULOSIS.

Demy 8vo. Pp. viii + 174. With 22 Figures. Price **10s. 6d.**, postage 6d.

PHYSIOTHERAPY IN GENERAL PRACTICE

By **E. BELLIS CLAYTON,** M.B., B.Ch. Cantab., Director, Physiotherapeutic Department, King's College Hospital.

"*The treatment by Physiotherapy of most conditions requiring this form of treatment in general practice is discussed in detail, and the book is illustrated by excellent diagrams and photographs.*"—GLASGOW MEDICAL JOURNAL.

Demy 8vo. Pp. viii + 235. With 7 Coloured Plates. Price **10s. 6d.**, postage 6d.

THE MIND IN HEALTH AND DISEASE

By **T. WADDELOW SMITH,** F.R.C.S.Eng., Senior Assistant Medical Officer, City Asylum, Nottingham.

The Harveian Lecture

ON

INDUSTRIAL FATIGUE.

Delivered before the Harveian Society of London on April 23rd, 1925,

By CHARLES S. MYERS, C.B.E., M.D.,
D.Sc. Camb., F.R.S.,
DIRECTOR OF THE NATIONAL INSTITUTE OF INDUSTRIAL PSYCHOLOGY.

For a member of the same College in Cambridge and of the same hospital in London as William Harvey, it is a special honour to be invited to give this address in his memory. Industrial fatigue must have existed in Harvey's time, but under conditions so widely different from those now obtaining that it could not attract public attention and could not receive such scientific treatment as is possible to-day.

Definition of Industrial Fatigue.

I shall be expected at the outset to define precisely what is to be understood by industrial fatigue. It will be urged that since the ultimate aim of science is measurement, an exact knowledge of what it is that we are endeavouring to measure must be essential if our procedure is to be scientific. But do we not measure electricity despite our ignorance of its nature? And may we not by statistical methods even measure a common factor affecting a number of different phenomena, without knowing anything whatever of the nature of that factor beyond the fact that it is a common determinant, among others, of those phenomena?

Two Groups of Tests.

Assuredly the earliest workers on the subject of industrial fatigue did not concern themselves with its definition or with any careful inquiry into its nature. They set about devising tests which would reveal its presence. Those tests fall into two groups. The first group consist of brief tests of efficiency which were applied to the worker at different times of the day or week, and compared in regard to their results. Thus the average of two or three successive grips of the dynamometer was registered, first, say, in the early morning, then at mid-day, next in the early afternoon, and finally at the end of the day's work, and the difference or lack of difference between the strength of the worker's grip at different hours of the day was held to indicate the presence or absence of industrial fatigue. Other simple tests were employed in the same way—such as a few reaction times, keenness of sight or hearing, the delicacy of discrimination between two near simultaneous touches of the skin or the speed of learning, so as immediately and correctly to reproduce a short series of numbers or letters. And when it became obvious that the worker could simulate fatigue by intentionally doing worse at the tests in the course of their application, tests were introduced which were independent of voluntary control, such as involved a record of the pulse-rate or of the time the skin took to recover its colour after being blanched by momentary pressure.

But another important complicating influence still remained—that of the feelings. The worker might be at one time annoyed or at another relieved by being interrupted in his work in order that these tests might be applied to him; in the early stages of their use he might be alarmed by the apparatus involved, or in later stages he might be bored by them. Such affective variations, together often with the effects of practice, could not fail to obscure the revelation of industrial fatigue, even if—as was tacitly assumed—the tests were competent to reveal its presence and to measure its degree commensurately with their results.

The second group of tests were in themselves tests of fatigability. A relatively lengthy task was imposed—e.g., repeated flexion and extension of a single finger-joint engaged in lifting a weight until the joint could no longer be moved, repeated additions of pairs of numbers, the erasure of a prescribed letter in printed matter, say for an hour, a work curve being obtained, movement by movement, or minute by minute, which was held to indicate the fatigability of the subject, the curves being compared at different times of the working day, week, or season. But here, again, the influence of practice often proved a serious practical difficulty. Moreover, the problem of whether, and if so how far, fatigue at a given occupation was local or general was overlooked. And the degree of correlation between industrial fatigue and the evidence of fatigue revealed by the tests was unknown and apparently unknowable.

Many of these tests, especially after experience sufficient to remove the complicating effects of practice, became so automatic and were carried out so unconsciously as to be incomparable with industrial conditions in which the work was more varied and required the exercise of a certain skill and judgment. The tests were necessarily of a very simple character, measured by quantity rather than by quality of output. In view of all these difficulties, it is hardly surprising that the interpolation of so-called fatigue tests brought discredit on the early attempts to estimate industrial fatigue.

Nature of Fatigue.

Let us, then, turn to a consideration of the nature of industrial fatigue, dealing first with occupations especially involving muscular work. Here, it might be thought, is a field in which the ergograph, recording flexion and extension of an isolated joint within the intact organism, might yield serviceable evidence of the extent of fatigue. Here, too, it might be expected—from the resemblance of ergographic conditions to those of the muscle-nerve preparation—that our knowledge of the physiology of muscle would render valuable help in its application to industrial fatigue. We have reason to believe that the isolated muscle tires because it no longer has sufficient manufactured material (of the nature of glycogen) at its command which will enable further contraction to take place, breaking down into lactic acid, carbonic acid, &c., or because the muscle-fibres have become clogged by the non-removal and the accumulation of such poisonous products of decomposition.

But the ergographic tracing is not a simple record of either of these conditions. For, when the subject has reached the stage when he is quite impotent to produce further movement of his finger, he will immediately be able to furnish another good ergogram, if the weight which his finger is lifting be slightly reduced. From another aspect, too, the stage of absolute exhaustion which he has reached is only apparent, so far as his muscle is concerned. It will still readily contract if the stimulus of an electric current be applied to his arm over the appropriate peripheral motor nerve. The so-called fatigue effects revealed by the ergograph are very largely of nervous origin, due to afferent impulses ascending from the tiring muscle and inhibiting the transmission of efferent impulses which would otherwise throw it into action. They are protective against truly muscular exhaustion, and we are ignorant of the relation between such nervous inhibition and the degree of truly muscular fatigue occurring. We do know that under conditions of severe general fatigue such inhibition may fail, and thus a better ergographic tracing—i.e., a larger amount of work—may be compatible with increased fatigue. Such an experience occurred to my knowledge during a prolonged series of ergographic records daily taken by the late Dr. Rivers, who one day felt so tired from an exceptionally arduous day's mental work that he was sorely tempted not to tire himself further with the taking of the usual evening's ergograph tracing. But, resisting the temptation, he obtained one of the best records of muscular work throughout the whole series of his experiments.

We have also to remember that the conditions under which the industrial worker carries out his daily work are very different from those under which an ergographic record is taken. The worker does not confine himself to the use of a single muscle. By varying his posture, as he tires, he often brings other muscles into play to carry out the same operations as heretofore. He does not work his hardest at each muscular contraction, as the ergograph demands of its subject. More or less unconsciously he adapts his expenditure of work to the length of his unbroken working spell or working day.

The fatigue which such a worker suffers is not merely or principally a fatigue of effort; it is also largely a fatigue of skill. There is no industrial work that is, strictly speaking, unskilled. For there is no occupation in industry in which there are not good and bad methods of carrying it out. The best worker is he who has become expert in the use of the best movements. He acquires his skill by coördinating visual, tactual, or auditory sensations with movements, by synthesising relatively simpler, previously acquired movements with one another so as to perform more complex movements, and by analysing and suppressing needless movements so as to obtain cleanness and economy of movement just as a clever artist eliminates all but the essentials in a sketch or caricature. Coördination, integration, and inhibition are thus the essential nervous processes for securing the minimal expenditure of muscular effort and for yielding the maximal efficiency of output. At the same time, the field of consciousness becomes reduced both in extent and in intensity. The need for widely diffused attention and for continuous judgment becomes replaced by the establishment and maintenance of an appropriate conscious attitude or posture in which the work is carried out to a large extent automatically. When fatigue arises, the discarded conscious attention to details is revived. Voluntary effort replaces intuitive behaviour, but with much less success. Output is reduced not only in quantity, but also in quality. The expert worker falls to the level of the inexpert worker. Old faults reappear. Finally, disorder replaces order of movement.

Moreover, apart from the fatigue of muscular contraction, there is a fatigue of the posture of the muscles employed, a fatigue of the central nervous "set" which is responsible for the preservation of the favourable posture, a fatigue, it may well be, of the directive process establishing that set. Lastly, not only are the various simultaneous movements integrated together by practice so as to form a single whole, not only is there this integration of a spatial kind, but practice also brings about an integration of a temporal kind. Successive movements are integrated together, and here the influence of rhythmical performance is of the greatest aid. The value of acquiring a proper rhythm in repeated movements can hardly be exaggerated. This kind of integration likewise breaks down in fatigue.

We see, then, that if, so far as the performance of movements is concerned, industrial fatigue is to be viewed in the light of a fatigue of acquired skill, we are far removed from an explanation of industrial fatigue in terms of muscular metabolism. The fatigue must be traced largely to disorders of nervous integration, inhibition, and coördination. Its site must lie in the central nervous system.

Illustrative Examples.

Two examples, illustrative of this conclusion, may be cited from the reports of the Industrial Fatigue Research Board. In the course of their investigations into the process of "buffing" Farmer and Brooke[1] obtained wattmeter records of workers roughing (removing imperfections and scratches from) spoons and forks throughout the day. These records enabled the experimenters to detect the varying number and duration of the strokes and the varying pressure with which the workers applied each spoon and fork to the polishing wheel. As the output diminished during the day's work the worker's strokes increased in number and duration, while the pressure with which the strokes were applied became greater. In other words, with the onset of fatigue, the worker began to use extravagant energy, although the output was diminished. The skilled worker became an unskilful worker, just as happens in sport with a tired eight or a tired golfer.

The second example[2] illustrates a natural corollary from our results—namely, that it is the less efficient worker who is most susceptible to fatigue. In their investigations in boot and shoe factories, Loveday and Munro observed that those workers who achieved a high output suffered far less than their relatively inexpert comrades from the fatigue of the week's work. Whereas the latter would reach their highest output at the middle of each week and fall off, often considerably, towards its end, the former would maintain their high level to the end of the week with very little or no diminution. We conclude that it is the unskilled and less productive worker who uses the most effort and who is the first to tire.

PHYSIOLOGY OF FATIGUE.

Industrial fatigue being thus pre-eminently due to fatigue of the central nervous system, we turn expectantly to our knowledge of the physiology of central nervous fatigue, but only to find an almost complete ignorance of the subject. So far as the white matter is concerned, nerve fibres are believed to be virtually indefatigable; the peripheral nervous impulse appears to be of a physical rather than a chemical nature; the metabolism of the brain and spinal cord has so far proved almost inappreciable in detectable effects.

The physiological study of the fatigue of reflexes has yielded strange results, inexplicable by present conceptions of its nature. Fatigue in the central nervous system, as mechanically conceived on the basis of the study of isolated muscle, appears to be safeguarded by "the interplay of opposed agents,"[3] those of excitation and inhibition, each of which must be regarded as a relatively separate, active process and presumably as separately amenable to fatigue.

We started by treating the human organism as a mechanical engine which becomes tired when it has no longer any explosive material at its command or when it becomes clogged with the products of its combustion. But we have been led to consider central nervous fatigue as consisting not so much in the wearing out of the processes of excitation and inhibition, as in a loss of coördination, a regression from later acquired skill to lowlier earlier levels of movement, the substitution of disorder for order, the loss of higher control, organisation, and direction. Further, physiology is at present powerless to lead us. It can only recognise the facts. Biology now admits that the living organism is something more than a mere mechanism, that mere chance variations are inadequate to explain the evolution of the living world, that order and direction, culminating in purposeful individual minds, have to be taken into account. We have reached the conclusion that industrial fatigue is primarily a breakdown in that order, a loss of coördination and direction, an impairment of that psycho-physiological feature which in its highest manifestation distinguishes the mental from the merely living, in its lowest the living from the purely mechanical organisation.

MEASUREMENT BY EFFECTS.

In our impotence to express this change in mechanical terms, we can only measure industrial fatigue by its direct effects. We can only safely study its effects by recourse, not to the interpolation of so-called fatigue tests, but to the actual industrial work curve. We need to measure output hour by hour throughout the working day and to study how the output rises and falls both in quality and in quantity at different hours of the day, on different days of the week, and so on. We study both curves of total output and curves of spoilt work for different kinds of work. We introduce improvements in environment—in illumination, ventilation, temperature, &c.—improvements in arrangement of the worker's material, improvements in the worker's posture and the number, nature, and rhythm of his movements, the introduction of rest pauses in a long previously uninterrupted spell of work, better selection of the worker according to his innate abilities and interests. And we separately study the effects of these changes, one by one, upon the work curve.

We know that when the worker starts his work he has to get into his stride, to warm up to his work, to overcome distraction, to settle down to a rhythmical method of working. We know that when he resumes work after a pause he also suffers at first from having to overcome such detrimental effects. But the psychologist does not confuse these effects with loss of practice. A few minutes' absence from work does not produce any loss of skill any more than does a few minutes' pause between the repetitions of a well-learnt poem produce a loss of memory. What is lost in a short rest pause is not loss of practice but loss of what the psychologist calls incitement and settlement.[4]

During a rest pause, moreover, the effects of fatigue disappear, and in general the beneficial effects of a rest pause so far outweigh the detrimental ones that an increase in output results despite the somewhat lessened period of time actually spent at work. Thus, in the operation of packing, Farmer and Eyre, experimenting on behalf of the National Institute of Industrial Psychology,[5] obtained more than a 5 per cent. increase of output after introducing a rest pause of seven minutes in the middle of the morning's and afternoon's work, although by so doing there was a reduction by 3 per cent. in the total number of hours worked. The National Institute obtained by similar means a similar result—more than a 5 per cent. increase of output was obtained by Miles and Bevington[6] in the process of polishing celluloid articles. Other increases, varying between 5 and 10 per cent. of output, are recorded by the Industrial Fatigue Research Board.[7]

We have yet to ascertain why rest pauses are apparently in exceptional cases of no avail. Where they have succeeded the workers have eagerly welcomed them, preferring definite organised rest pauses to the irregular periods of rest which they would otherwise have surreptitiously taken in a long officially unbroken spell of work. Rest pauses require for their successful introduction a careful preliminary study of the work curves, so that the best moment for their introduction and their duration may be determined. The work curves also require study for an accurate realisation of the effects of the rest pause. Mere increase in output is not a sufficient result to please the industrial psychologist. He demands not merely a higher *level* of curve, but an improved *form* of curve. Particularly he wants to avoid a severe fall of the work curve towards the end of the working spell.

The good effects of a rest pause, as, indeed, the good effects of reducing the total number of hours worked, may not be fully evident until several weeks or even months have elapsed. The worker needs time to become adapted to the more advantageous conditions of his work. Ideally each worker needs a different length of rest pause and a different moment for its introduction in order to produce its best effects. In practice, however, the workshop, like the school class, has to adopt procedures which are most advantageous to the majority of its members.

MENTAL FACTORS.

The work curve is likewise complicated by the presence of spurts—one of which is specially apt to occur when the end of a piece of work or the end of a spell of work, or the approach of payment is in sight. Besides the end spurt there may also be an initial spurt, when the worker comes fresh to his task with a degree of energy which soon falls off after the first few minutes. The work curve is also marked by spurts and falls at other periods, due to various mental and physical influences.

Of these mental factors the most important are of affective nature. The worker's feelings alter at his work. The feelings are of enormous importance in influencing mental and muscular work. On the one hand, they may conflict with the general attitude he has to maintain and the efforts which consciously or unconsciously he has to expend; or, on the other hand, they may assist in those directions. Irritation and boredom are obvious examples of the former, contentment and interest of the latter.

The influence of feelings of pleasure and displeasure and of excitement and depression on the muscular effort of which a person is capable have long been recognised by physiologists and psychologists. But the influence of conflicting feelings on the orderly character of mental and central nervous processes was only adequately realised after experience of the psycho-neuroses arising in the course of the war. The phenomena of disorder and regression there met with are but a pathological exaggeration of the same phenomena which I have stressed earlier in this address as occurring in industrial fatigue.

Just as efficient muscular work demands the maintenance of a favourable posture, so efficient mental work demands the maintenance of a favourable attitude. This attitude is, of course, maintained more easily in states of contentment and interest, less readily in states of resentment and boredom. So long as the worker is happy and interested, the favourable attitude can be preserved without effort; its preservation involves the successful inhibition of all antagonistic, incompatible attitudes. Such inhibition is apt to tire when interest fails. Discordant ideas or movements are no longer automatically suppressed. They become manifest and themselves inhibit industrial work. Conscious voluntary effort has to be invoked in order that the mental or motor task may be continued. As this wearies, boredom is felt and the need for a change of attitude becomes imperative.

We now realise how far the boredom arising from an uncongenial task may be safeguarded by a more careful selection of the worker. Too intelligent a worker for the kind of repetitive work in which he is engaged may be as unsuitable as a worker who has not sufficient intelligence for another job.[8] The work must be adapted not only to the level of general intelligence, but also to the special abilities of the worker. As a general rule, the dull worker prefers a more monotonous job. He does not want change. He safeguards himself against boredom by recourse to the phantasies of day-dreaming, to conversation, song, &c.

The effects of boredom are at first those of localised fatigue. They may be dispelled by a change of work. It has recently been found by Vernon and Bevington[9] that changes of muscular posture are extremely effective in preventing the signs of fatigue. So, too, the change of mental attitude produced by a change in the character of work may be fully as effective as the introduction of a rest pause. In one investigation Miles and Skilbeck, on behalf of the National Institute of Industrial Psychology, obtained an increase in output amounting to 14 per cent. by allotting two short periods of the morning's and afternoon's work to the collection of material by the worker, instead of distributing that collection, as had happened for the most part previously, over the working day. Similar results have since been obtained in laboratory and factory experiments conducted by Vernon and Wyatt for the Industrial Fatigue Research Board.[10]

[9] Industrial Fatigue Research Board, Report No. 29 p. 48 ff.

How far boredom is an important factor at the present day in reducing industrial output cannot easily be determined. The worker's initial spirit of " buck " and interest upon entering an occupation may be so easily broken after a few weeks' engagement on routine work that he soon becomes adapted to carry out his work by recourse to those safeguards against intolerable boredom which I have already mentioned. But if actual boredom is lacking, there can be no doubt that a vast increase in quantity and quality of output could be effected if steps were taken by introducing adequate incentives to increase and to maintain the worker's interest, and hence his conscientiousness. A careful study of the most effective incentives to efficient work is therefore of the greatest importance.

Incentives to Efficient Work.

One of the National Institute's investigations[11] affords a striking demonstration of the improvement upon quality of output which may result from alleviation of the workers' irritation, annoyance, and worry. It was concerned with the breakage of china in one of the tea-shops of a large catering firm, and its success was largely due to an early recognition by Miles and Eyre, the investigators, that carelessness was not an adequate explanation of the breakages. Records were carefully taken every two hours throughout the day showing where, when, and what articles were broken. Danger points were thus revealed, and so far as possible removed. But the investigators' attention was mainly directed to overcoming the *psychological* causes of breakages, diminishing discomfort, overstrain, and sources of irritation, and facilitating the flow of work. Curves of breakage frequency, in other words of spoilt work, were constructed both before and after the changes recommended by the Institute had been carried out. Not only was there a diminution of over 53 per cent. in the number of breakages, not only was the curve of spoilt work at a lower level throughout the day, but it showed a far better form. The previous well-marked rise of the curve towards the end of the day's work disappeared. We may reasonably conclude, therefore, that removal of the sources of worry and irritation materially reduced the workers' fatigue. They expressed unfeigned appreciation of the improvement in working conditions introduced by the Institute.

The curve of spoilt work throughout the day has been shown by Ryan and Sargant Florence[12] to be characterised by the same features as that of output, though, of course, in inverse direction. It tends to be greatest during the initial and final hours of the morning's or afternoon's spell of work. It is also greatest among the less expert workers. The causes and hourly frequency of industrial accidents show a close resemblance to those of spoiled work. Over-pressure and irritation, especially when accompanied by fatigue and inexperience, increase the hourly frequency of accidents. Mere fatigue alone may not do so. For the worker may for a time at least work equally cautiously, but at a far lower level of output. It is when he is unduly pressed or excited that spoilt work or accidents become more frequent, and especially when such over-pressure, irritation, and worry are so great as, or have continued long enough, to be associated with fatigue.

Fatigue or Inhibition?

At the outset we might have been disposed to define industrial fatigue as that result of previous industrial work which is manifested as a diminution in output. But, as has been shown, fatigue may temporarily result in an increased amount of work due to the tiring of higher-level inhibition and control, and it may result from many other causes than that of previous industrial work. The worker may for quite other reasons come to his work in a fatigued state. His lack of training, his use of needless movements, his whole mental and physical environment may be the true causes of his fatigued condition rather than the number of hours which he has already worked.

Further, diminution of output as the work continues may result not only from fatigue, but also from lack of incentive or boredom, resentment, and worry —causes which if prolonged and resisted will ultimately cause fatigue, but the removal of which in their early stages of occurrence will at once produce a rise of output. Their adverse influence on output is initially due to temporary inhibition. How are we to distinguish industrial fatigue from inhibition? Only, I think, by observing the effects of removing their respective causes. If the reduction of output at once disappears, we may justly attribute its causes to previous inhibition. If the reduction of output is gradual, we may (with less certainty) attribute its cause to previous fatigue.

In the majority of cases under present-day conditions industrial fatigue is not to be reduced by shortening the hours of the day's work. It is to be combated rather by the avoidance of too long uninterrupted spells of work, by the introduction (after careful study of the work curve) of rest pauses, and of change of work and posture, by determination of the best movements of the worker, by systematic training of the worker in those movements, by selection of the worker so that his occupation is adapted to his innate abilities, by the abolition of causes of needless resentment, irritation, and worry, by the introduction of suitable incentives to work, by the provision of a good physical environment in regard to illumination, temperature, humidity, ventilation, food, &c.

As we have seen, industrial fatigue is too complex, and our knowledge of the physiology of the nervous system is too rudimentary, to allow of a definition of its character in physical and chemical terms. Indeed, it may be of a nature that forbids complete definition in the language of pure mechanism. At present it can only be studied and estimated by means of industrial work curves—curves of output and curves of spoilt work, indicating variations in the quantity and the quality of the worker's products. We must never forget that industrial fatigue involves not merely a diminution in the quantity of the worker's available " energy," but also a lack of harmony, a disorder of the various nervous processes which determine his performance of mental or bodily work.

Middlesex Hospital Medical Society.—The annual special meeting of this society will be held at the Middlesex Hospital, London, on Tuesday, May 12th, at 8.15 for 8.30 p.m., when Lord Justice Atkin will deliver an address entitled Medicine and Law.

Health and Psychology of the Child.—A series of six lectures on this subject, addressed to matrons of day nurseries, children's nurses, teachers, and mothers, will be given under the auspices of the National Society of Day Nurseries at Carnegie House, 117, Piccadilly, London, W., on Tuesdays at 7 p.m., from May 19th to June 23rd. The lecturers are Dr. Alice Hutchison, Dr. Sloan Chesser, Dr. Kenneth Dickson, and Miss Liddiard.

THE PRACTICE OF ARTIFICIAL LIGHT-BATH TREATMENT.

BY J. H. SEQUEIRA, M.D., F.R.C.P. LOND.,
F.R.C.S. ENG.,
PHYSICIAN TO THE SKIN AND PHOTOTHERAPY DEPARTMENTS,
LONDON HOSPITAL;

AND

W. J. O'DONOVAN, O.B.E., M.D., M.R.C.P. LOND.,
CHIEF ASSISTANT, SKIN DEPARTMENT, LONDON HOSPITAL.

THE value of sunlight in the treatment of certain forms of tuberculosis [1] [2] and of rickets [3] is established. It is also recognised that artificial light can be utilised to replace and supplement the sun's rays.[4] The object of this paper is to place on record our experience with artificial light-baths during the past two and a half years in the hope that it may be of assistance to other workers in the same field. Before discussing the practical aspect we think it will be of interest to review briefly the important biological research which has been carried on pari passu with the clinical observations.

Historical Survey.

The Romans appreciated the benefit of the sun-bath, though it does not appear that they attributed any therapeutic properties to it. The solarium was either on the top of a flat-roofed house or a gallery above a porch, and though open all round was often covered by a roof. Here a portion of the day was spent in "slacking" in the sun.* The close resemblance of the Roman solarium to the sun-baths in the Higher Alps is sufficiently obvious.

The earliest reference in literature to the actual use of light in the treatment of disease is found in the well-known passage in the "Rosa Medicinæ" of John of Gaddesden (1280–1361),[5] who claimed to have cured a royal prince of small-pox by keeping him in a chamber from which all radiations but the red were excluded. This was probably based on some previous experience and may have come from the East, where such a measure is believed to have been used in the remote past. Finsen, to whom we owe so much in the scientific development of phototherapy, was of opinion that the essential factor in red light treatment (as used in variola) was the exclusion of the ultra-violet rays,[6] but some recent work with a neon lamp, which gives red rays, suggests that these radiations may themselves have a definite therapeutic effect.

Therapeutic Activity of Different Parts of Spectrum.

It has been determined that the various parts of the visible and non-visible spectrum have different therapeutic activities, and in time it is hoped to be able to state definitely what portion of the spectrum is responsible for the clinical phenomena observed. Experiment has shown :—

1. That infusoria can be immobilised by exposure to a mercury-vapour lamp, but that the time required is lengthened by simultaneous exposure to red rays (Hill and Eidinow[7]). This antagonism has also been observed by Hess in experiments on rats with combined radiations.

2. That rats fed on a diet deficient in vitamin A cease to grow normally in from seven to ten days. If rats so fed are subjected for ten minutes every second day to the radiations of a mercury-vapour lamp the growth of the animal is normal for from 35 to 50 days. After that symptoms of vitamin-A deficiency occur and xerophthalmia develops.[8]

3. The development of rickets is prevented in rats fed on a rickets-producing diet by a daily exposure for 15 minutes to a mercury-vapour lamp.[9]

4. That the bactericidal power of a rabbit's blood against staphylococcus can be greatly increased temporarily by exposing the shaved skin of the animal to the mercury-vapour lamp. This phenomenon lasts for two or three hours, but can be reproduced by further exposure to the source of light. This reaction is not restricted to epidermal cells, for an exposure of the ileo-cæcal portion of the small intestine gave rise to a similar increase in the hæmo-bactericidal power. Controls treated in like manner without irradiation gave negative results.[10] It has also been demonstrated by Colebrook that the hæmo-bactericidal power in man may be increased by light-baths, but that in some instances the exposure of the whole body to actinic rays may diminish this power.[14] This operation may explain why some cases of pulmonary tuberculosis "flare up" after sun-baths, a contingency well recognised in sanatoria. Colebrook, Hill and Eidinow find that the hæmo-bactericidal power in man does not increase unless an erythema is produced.[12] This observation suggests to us that there must be some other explanation of the benefit derived by tuberculous subjects from light-baths, for many of our patients have shown marked clinical improvement without the production of an erythema.

Pigmentation.—We find that clinically we can produce more rapid pigmentation with the carbon arc than with the mercury-vapour lamp, and in the majority of patients the pigmentation after carbon arc treatment is of a redder brown, while that of the mercury-vapour lamp is greyer. Some patients, both brunettes and blondes, do not pigment at all, and in spite of this they show clinical improvements.

5. An instrument has been designed by which the ultra-violet light may be measured. It consists essentially of a wedge-shaped glass envelope containing a standard solution of acetone methylene-blue, and the degree of bleaching has been standardised by the exposure required to kill hay infusoria.[11]

Clinical Observations.—Actinic light is used in treatment in two ways: (1) local treatment by concentrated light, particularly applicable to the form of tuberculosis of the skin known as lupus vulgaris; and (2) by subjecting the whole body to the sun's rays or to a powerful source of light rich in actinic radiations.

Local Treatment by Concentrated Light.

In his early experiments Finsen used the sun, focusing its rays through a large lens containing a blue solution on the affected area of skin. At the focus was placed a compressor formed of a ring of metal with two plates of rock crystal. The compressor was used to render the parts anæmic, it having been found by experiment that the red colouring matter of the blood prevented the passage of the actinic rays of light. The compressor was also used to cool the parts, and for this purpose a current of cold water was kept constantly circulating through it. Without this cooling the patient was unable to bear the heat produced at the focus of the sun's rays. It was soon found, however, that in Copenhagen, as in other countries in northern latitudes, the sun was too unreliable as a source of illumination, and powerful electric arcs were substituted for it. The light from these arcs was passed through a series of lenses in a telescope tube and focused on the affected area of skin. The compressor was used as in the sun treatment. By the original Finsen apparatus eight patients were treated at a time. A modification devised by Reyn for the treatment of one patient on the same principles has been found equally efficacious. Trials were made of other illuminants—e.g., a lamp with iron poles giving a highly actinic light was devised, but was eventually discarded.

Mention must, however, be made of the ingenious Kromayer lamp which is of considerable utility in certain types of case. This consists of a U-shaped envelope of rock crystal containing mercury vapour. It is enclosed in a capsule of metal with a rock-crystal window. Through the outer capsule a constant current of cold water is passed. The rays developed in the mercury vapour are highly actinic and the window is pressed firmly against the part to be treated, so that the area is rendered anæmic and can thus be penetrated by the actinic rays. In our experience the Kromayer lamp has a sphere of usefulness particularly for lesions on the body and limbs.

---

* We are indebted to Dr. Brownrigg, headmaster of Magdalen College School, Oxford, for interesting information on this point, and a reference to a criticism in Plautus (Miles Gloriosus) to a house which had neither a garden nor a solarium.

If treatment is carried out with a careful observance of Finsen's technique, from 60 to 70 per cent. of cases of lupus vulgaris can be cured. The inflammatory reaction following the application of concentrated actinic light destroys the infecting organisms, and replaces the diseased tissue by a soft, supple, healthy cicatrix. The failures are due to (*a*) extensive disease of the mucous membranes, especially of the nasal cavity, and (*b*) a type of the disease too active for the necessarily slow treatment to keep pace with its extension.

The Light-Bath.

The sun-bath was originally introduced for the treatment of surgical tuberculosis in Switzerland by Bernhard,[13] and the clinical application has been developed by Rollier. At first it was thought that the undoubted benefit which followed the exposure of the nude body was mainly due to the high altitudes, but it is now known that the important factor is the light. In the Alps the air is clearer than in lowland countries, and there is less absorption of the actinic rays by the atmosphere. At the seaside the actinic value of the sunlight on clear days is higher than inland, but in winter in northern latitudes the chemical activity of the sun's rays, even on bright days, is low. Hence the necessity for artificial illuminants.

Lamps in common use are (1) large carbon arc-lamps with or without tungsten paste cores ; and (2) mercury-vapour lamps. Tungsten arcs have also been used, but we found that these had practical disadvantages. Our remarks apply to carbon arcs with tungsten paste cores and mercury-vapour lamps.

Apparatus.

1. We do not advocate the use of any particular *source of illumination.* We have to consider expediency as well as theoretical light-values. For instance, we must modify our methods according to (*a*) the time that the patient can spare for treatment ; (*b*) the pressure of numbers ; (*c*) the convenient formation of manageable groups of size and age (we find it inconvenient to treat adults with children owing to the level at which the source of illumination is placed with regard to the patients) ; (*d*) infectivity—it is unwise to place a patient with cough or discharges in proximity to other patients ; (*e*) whether the patient can come to the lamp or a portable illuminant must be used (the voltage available in the latter case is an important factor) ; (*f*) the standard of training of the assistants. One form of illuminant is fool-proof, while another—e.g., the mercury-vapour lamp—requires trained and informed care.

2. *Type of Illuminant.*—No consideration whatever can be given to any light which is glass-enclosed. Glass is almost impermeable to ultra-violet light.

Carbon Arc.—Small or large carbon-pencil arcs are equally valuable if the law of inverse squares is borne in mind—i.e., a small group or single patient placed before a 25-ampère lamp, or ten children or eight adults around a 75-ampère lamp would give equally good results. If carbons with a tungsten paste core are used a light of high actinic value is obtained, a light whose spectrum more closely approximates that of sunlight than with any other form of illuminant. Such lamps are mechanically dependable, owing to their long use by electrical engineers as public illuminants. The only difficulty is the regular approximation of the carbon pencils as they burn away, and this is efficiently met with in any type designed for continuous use. An arc that will burn for four hours without replacement of carbons is all that is required. The group treatment of patients around an arc lamp is attended by heat and stuffiness to an extreme degre. This can be overcome by efficient ventilation, and when this is impossible the discomfort ceases if an efficient ozonising apparatus is installed. For convenience of electrical supply two 24-ampère lamps can be used together as a unit rather than one lamp of higher ampèrage. A lamp of high ampèrage might require the installation of a motor transformer.

Mercury-vapour lamps have certain advantages. The initial cost is low, the lamps are portable, and the current required may be obtained from ordinary lighting circuits. No mechanical attention is necessary during the ordinary life of the "burner," which is approximately 1000 hours. It is fragile, replacement of the burner is expensive, large-group treatment is impracticable, and the best results have always been obtained by treating patients singly or at most in pairs. Great care is needed for the protection of the eyes of both patient and attendant, as painful conjunctivitis may follow a very short exposure. Children, particularly, require constant watching under this light, as they tend to interfere with the apparatus and approach too near to the source of light. Careful timing here is of first importance, and is to be obtained by the use of a cardboard clock-face, the hands of which can be set for the time of the determination of the dose, and by always having the patient facing a dependable clock and telling him that when his time arrives he must leave the lamp. This precaution is taken in case the nurse should by any accident be prevented from giving the necessary warning. We prefer this method of working to the installation of an automatic cut-out worked by a clock, since the frequent interruption and restarting of the lamp at intervals that may be as short as two minutes, throw an undue strain on its construction, and, furthermore, at each restarting time is lost while waiting for the incandescent vapour to acquire its full actinic value. When absolutely new the reaction is more intense than when it has been in continuous use for 24 hours, but after that, certainly up to 600 hours, its reaction has appeared to us to be remarkably constant. In an old burner the quartz becomes opaque, and longer exposures are tolerated by the patients. It is therefore important to bear this in mind when replacing an old burner. The exposures then should be re-timed as from the start.

Clinical Dosage.

Generally the initial dose, which can be borne with comfort, should give rise to no more than an evident reddening of the skin and a not unpleasant conscious tingling. Experience of initial doses over the last two and a half years has never shown any ill-effects of an exposure of half an hour to the carbon arc light or of two minutes to a 6 in. mercury-vapour burner. It is a fact that after an exposure of two minutes a patient ceased to attend the department when a doctor called in hinted at a diagnosis of scarlet fever, but the patient attended the day following and received a second "erythema dose" without distress or injury to the skin. With either of these initial doses desquamation, in the form of large dry flakes, may be widespread or may not occur at all. We have never seen blisters form, however intense the reaction within this timing, or however widespread the desquamation may have been. From our observation more severe reactions are given by the skin of brunettes, who also in turn exhibit far more intense pigmentation as time goes on. We meet with blondes whose reaction, at first acute, after many doses is often imperceptible, yet the improvement in their physical state goes on. It has been suggested that a trial dose to a limited area of skin would be of assistance in the dosage of new patients. We have not yet found any disadvantage in proceeding on the lines of gradually ascending doses from our ascertained safe initial exposure.

The stages of increase are, for administrative convenience, ascended at weekly intervals. The carbon-arc exposure is increased by half an hour at a time up to a maximum of four hours per diem. If at any time the skin is noted as being erythematous, with or without pigmentation, the dosage is not increased. In the mercury-vapour cases the initial two minutes to each side of the body is increased weekly by a minute to either side, to a maximum of 20 minutes to each side.

Intermissions due to illness, holidays, menstruation, call for watchfulness. An interval of up to four days calls for no alteration in the time of exposure. A month certainly means a resumption of the initial dosage—e.g., half an hour of the carbon arc or two minutes of the mercury vapour. An intermission of a fortnight requires a halving of the maximum then reached. Omission of this precaution has given rise to painful severe erythemata. In practice we find it unnecessary to differentiate between the children and the adult patients as regards the initial exposure. For rickety babies we have not exceeded a maximum exposure of two and a half hours to the carbon arc. The standard distance of the patient's exposed skin from the source of light is assumed in all cases to be three feet, and so far we have applied this system of dosage to all types of disease submitted, but enlarged experience may lead us to introduce modifications. We think it is an advantage to maintain the patient in a sitting, standing, or recumbent position throughout his treatment. Exposure of ambulant patients appears to offer no special advantages. Areas of skin reacting from any local treatment or in an ulcerated condition, are carefully protected by a dressing while the rest of the skin is exposed. If this is not done the patient will complain of pain and discomfort, and there is no appreciable therapeutic benefit.

Protection of the eyes in all cases is necessary when the front of the body is under treatment. Smoked glasses in practice are always discarded for brown-paper masks. For small children closely-fitting leather and elastic eye-shades are used in which are inset deep-tinted glasses.

Physiological Effects.

The physiological effects observed on patients while exposed or after exposure to the light-bath made in our clinic are as follows:—

1. The *basal metabolism* was examined in a number of patients before and after light-bath treatment by Dr. Argyll Campbell, of the National Institute for Medical Research. No change was observed in the patients examined.
2. *Blood Counts* were made in a number of patients but no material alteration was noted. In some there was a slight increase in the leucocytes.
3. *Body Weight.*—If below the normal the body-weight was found to be increased by light-bath treatment.
4. *Growth.*—In children it was found that the rate of growth increased to but not beyond the normal.
5. *Mentality.*—Improvement was noted in all cases. Dull, lethargic patients became bright, and took an interest in their condition and appearance.
6. *Temperature.*—No change was found in the body temperature during or after the sittings.
7. *Pulse.*—The pulse-rate was unchanged.
8. *Respiration.*—The rate of respiration was not altered.
9. *Blood Pressure.*—Finsen was of opinion that hyperpiesis was directly affected; in fact, his early work on light-baths was directed specially to the treatment of high blood pressure. We found no change in patients with a normal blood pressure.
10. *Thirst.*—Our patients constantly complain of thirst.

Management of a Light Treatment Clinic.

The management of these clinics presents no difficulties that need prevent their widespread multiplication, save only that of initial expense and cost of running. The Ministry of Health have power to sanction contributions towards the cost of this installation and its upkeep by local authorities, but, naturally, the Ministry would be consulted in advance. Voluntary hospitals can come to arrangements with local authorities for "per capita" or for annual grants. The local M.O.H. is, of course, a mine of information as to the best manner in which to set this machinery in operation. Light clinics may be established as part of the armamentarium of a general hospital or infirmary. They may be set up for a special type of case—e.g., lupus—or for a special clientèle, as is found in a children's clinic, or sanatorium, or other specialised institution, where it may be used as a supplement to a general scheme of sunlight therapy.

Selection of Cases.—The majority of patients needing light treatment will be unable to pay for this during the necessarily long period of its continuance. External aid is a necessity if the clinic is to work successfully. Furthermore, continuity of attendance is essential. In all these matters coöperation with the local authority is of the greatest assistance. In some instances all that is necessary is the provision of a railway season ticket, in others a lodging allowance. The provision of hostels in connexion with clinics attached to general hospitals is now being considered. Attendance of patients can be stimulated by health visitors and by school nurses. Early cases are picked out for treatment by school medical officers, and others by tuberculosis officers and infant welfare clinics, while the majority have been and will be sent for treatment by the watchful general practitioner.

The choice of patients to be treated must be left, naturally, to the discretion of the medical man in charge of the clinic. In practice we find it impossible to take on cases, however suitable, unless and until arrangements have been made to ensure the regularity and continuity of their treatment from the outset.

Briefly, the types of case likely to benefit by light treatment in a general light clinic are: (1) tuberculosis of bones and joints, of glands, of the peritoneum, lupus vulgaris of the skin and of the mucous membranes; (2) rickets; (3) blood disorders; (4) neurasthenia; (5) some forms of chronic arthritis; (6) *B. coli* pyelitis. Experience may add to these.

Cases of pulmonary and laryngeal tuberculosis should be treated only in institutions devoted to this special work, not only on account of their contagious nature, but owing to their need of special dietary and hygienic care, and the need of expert clinical supervision. No surgical case should be admitted unless referred by a competent surgical authority. We have had sent to us cases of spinal caries still needing orthopædic support and cases of rickets that required operative or instrumental correction of deformity. Blood diseases also must be watched by a hæmatologist.

Staff.—The medical officer needs the assistance of a fully-trained nurse as the patients come at all hours of the day, and, in our own experience, have arrived with measles, chicken-pox, diphtheria, herpes zoster, encephalitis lethargica, and minor fractures.

Education.—Owing to the necessity of the daily treatment over a long period of time the need of educational care must be shouldered. Illiteracy and indiscipline are bound to occur in children lodged for long periods away from home. Owing to the keenness of the London educational authorities all our non-contagious children of school age may now attend school for half the day. But arrangements have still to be made for the education of children coming from a distance and living in approved lodgings, in the neighbourhood of the clinic.

Reports.—To secure the willing coöperation of boards of guardians it is necessary to make careful clinical reports which we find it advisable to supplement by photographs. It is obviously to the advantage of the contributing authority to be fully informed of the attendance and progress of cases for which they have assumed responsibility.

We never allow ourselves to forget that diseases must be attacked from all sides at once. Rickets calls for dietetics as well as light treatment; lupus needs local as well as general therapy; tuberculous adenitis may need tuberculin injections; surgical tuberculosis may require aspiration or operative measures.

Light therapy, then, is a new weapon in the armamentarium of medicine, but the great convenience of concentrating patients in a special clinic has the danger that other measures valuable in expert hands may be neglected. We realise daily the great advantages that we as well as our patients reap by the fact that all the laboratories and specialised services of a general hospital are immediately available.

LIGHT IN THE PREVENTION OF RICKETS.

A Paper read at the Fourth International Congress of Thalasso-Therapy, held at Arcachon, April 27th to 29th.

BY FRANCIS HOWARD HUMPHRIS, M.D. BRUX., F.R.C.P. EDIN., D.M.E. & R. CAMB.

RICKETS has been called either a calcium-deficiency disease or a vitamin-deficiency disease, and it may be that it is either or both of these ; but is it not essentially a *light-deficiency disease ?* And therefore does it not follow that the prevention and cure of the malady lies with *light-sufficiency ?* I think that the time will come when it will be generally acknowledged that light can prevent rickets as surely as vaccination can prevent small-pox, and is as valuable a means of cure as is antitoxin in diphtheria. The procedure, if simple, involves much time and a certain amount of trouble, but as a therapeutic possibility, surely well worth while.

Rickets is one of the diseases most amenable to the ultra-violet energy, and one in which the therapeutic value of this agent has been proved beyond doubt. For over 20 years experimental and clinical proofs have been frequently recorded. Literature, which, as a rule, is scanty where ultra-violet light is concerned, is prolific where this form of therapy is employed in rickets. Thirty-four years ago Dr. Theobald Adrian Palm published his views on the relation of sunlight to rickets,[1] and from then till the present time the medical journals have been publishing facts and results of ultra-violet radiation in the treatment of this disease, so that it would seem superfluous to enter fully into the subject here, and to discuss it superficially would be unsatisfactory.

The whole case may be summed up, somewhat baldly perhaps, by two definitions : (1) Rickets is a disease or aberrancy of the bony tissues due to, or characterised by, a calcium and phosphorus deficiency as well as by a lack of the fat-soluble vitamin A. (2) Ultra-violet therapy raises the calcium and phosphorus content in the body, and also increases the energy of the fat-soluble vitamin A. If the accuracy of these two definitions be admitted, it would seem that ultra-violet radiation is valuable in the pathological conditions shown in rickets.

Light and Metabolism.

The therapeutic action of ultra-violet radiation on metabolism opens up a wide field. It is known that these rays are absorbed by the blood, but we do not know how the end-products, resulting from the changes in the blood set up by this absorption, are stored, or in what manner or form these products are set free in the tissues. But that metabolism is profoundly and beneficially affected by them is now established beyond doubt. The good effect may be due to the chemical changes in the blood which follow the administration of ultra-violet rays. One of these changes is that the calcium content becomes higher, and another is that the concentration of inorganic phosphorus is increased by its means. The phosphorus and calcium increase in the blood is probably due to absorption of these salts from the bowel. It would therefore seem to be a logical corollary that, if an additional quantity of these salts were introduced into the bowel, the greater would be the opportunity for the ultra-violet radiation to abstract it therefrom.

It is probably mainly due to these chemical effects that ultra-violet radiation is productive of such good effects in rickets. This disease has in many cases been prevented and checked by the use of ultra-violet rays. Rats kept in darkness and deprived of certain food factors, notably vitamins, will develop rickets. If some of these rats be exposed to ultra-violet radiation, the diet remaining unaltered, the development of rickets in them is checked. The calcium and phosphorus content in the blood is responsible in a great measure for the integrity of bone structure, and for the growth and calcification of the skeleton. In this connexion it is interesting to note that Huldschinsky in 1919 placed it on record that at the Oscar-Helene Home for curing crippled children at Berlin ultra-violet radiation was more effectual than sunlight and cod-liver oil. He says: "Cod-liver oil as well as sunlight were found to be exceedingly slow in their action, the exposure to ultra-violet light yielding incomparably better results." [2]

Experiments with ultra-violet light on animals will illustrate the close relationship between light and diet in the ætiology of rickets, and show how the chemical changes, effected by radiation, produce good results. When the diet remains a constant standard rickets-producing diet, rickets will either develop or not, according to the dosage of light. Thus it was found that raying for two minutes daily with the mercury-vapour lamp at a distance of three feet afforded protection. Raying for only one minute was insufficient. Four minutes sufficed when a carbon-arc lamp was used at this distance, but two minutes were not long enough. There can be little doubt but that the same reciprocal relationship between light and diet prevails in regard to infantile rickets.

Calcium and Phosphorus Concentration of Serum.

A very striking table is quoted by Hill showing the percentage of calcium and inorganic phosphorus concentration of the serum of rachitic children before and after exposure to light. The figures are in milligrammes per 100 cubic centimetres of serum.

Calcium and Inorganic Phosphorus Concentration of Serum of Rachitic Children Before and After Exposure to Sunlight.

1922.	Calcium.	Phosphorus.	Product.	—
From June 10	8·8	2·8	30	Marked rickets.
to Aug. 2	11·1	5·0	55	Definite healing.
From Aug. [illegible]	11·0	3·0	33	Moderate rickets.
to Aug. 24	11·2	5·9	66	Healed rickets.
From Aug. 11	10·6	3·0	32	Rickets.
to Sept. 7	9·2	5·9	54	Healed rickets.
From Aug. 11	9·3	2·8	26	Active rickets.
to Sept. 7	9·8	6·4	64	Definite healing.
From Aug. 16	9·3	2·5	23	Rickets.
to Sept. 7	9·8	5·9	58	Healing.
From Aug. 18	9·8	2·5	25	Marked rickets.
to Sept. 7	9·2	6·5	60	Definite healing.
From Aug. 21	7·9	3·1	25	Rickets.
to Sept. 7	9·0	5·1	46	Healing.

Some two years after this table was presented, very interesting results were published [3] of research work undertaken by Grant and Gates of the Rockefeller Institute. These bear out Hill's figures in a remarkable manner. The experiments consisted in exposing light-coloured, or albino rabbits to ultra-violet radiation for half an hour daily at a distance of one metre. The rays caused erythema with its usual sequelæ, desquamation and moderate pigmentation. The examination of the calcium metabolism gave the following results. It was found that the average concentration in the groups having been exposed to ultra-violet radiation for five, six, and seven weeks was over 12·7 mg. per 100 c.cm.

of serum, as compared with an average of 11·9 mg. per 100 c.cm. for 60 normal control rabbits.

In another set of experiments rabbits were given increased exposures of ultra-violet radiation daily over a period of four weeks, and in these animals the blood-calcium concentration rose from 11·9 mg. per 100 c.cm. of serum before exposure to 12·2 mg. on the twelfth day, 13·5 on the twenty-second day, and 12·9 at the end of the experimental period. It was noted that the later figures in both these sets of experiments showed a somewhat lower level in the calcium content. This is probably due to the protection afforded by the skin pigmentation caused by the ultra-violet light.

Effects of Light on Endocrine Glands.

These experiments show a further point of interest which has a distinct bearing on the subject, and to which I will briefly refer. It is this. The weights of the endocrine glands and testes all increased during the treatment. These were all recorded and the changes compared with the normal controls. The parathyroids showed the greatest hypertrophy, the percentage in their increase varied from 14·1 to 51·1 per cent. This increase in weight was due to a true hyperplasia of the parenchymatous tissue. The normal relationship between the parathyroids and calcium metabolism is already established, but these experiments are important as showing the effect of ultra-violet radiation upon them both, and, as the authors say, whether the light acts primarily on the absorption and excretion of calcium, and so causes a rise of the blood calcium, which results in a hypertrophy of the parathyroid gland, or whether the radiation primarily affects the glands themselves, remains to be determined. But this determination may rest for the present. The fact of paramount importance is that ultra-violet radiation has the power to raise the calcium content in the blood, and is a reliable therapeutic measure which will cure and prevent rickets. This being established, let us touch briefly on the technique of the practical prophylaxis of rickets. The treatment should begin as soon as pregnancy is proved. In the parturient female an increased calcium content is a consummation most devoutly to be wished. There is normally a great drain upon her calcium metabolism, as is often evidenced by dental trouble, and, owing to this drain, the seeds of rickets may be sown in the child before ever it is born. Hence, both for her own welfare, and that of her unborn child, let the expectant mother have some form of light therapy regularly for the duration of her pregnancy. Apart from being an insurance premium against the production of unhealthy offspring, the mother will experience a sense of health and well-being not always obtaining among women labouring with child, but which usually accompanies the administration of general light therapy.

Furthermore treatment by light should be continued throughout the period of lactation. What better prophylactic agent against the occurrence of rickets could be desired than the maternal milk rich in calcium salts? Steenbock and Black [4] have shown that if a rat's food ration, deficient in fat-soluble vitamin, were exposed to ultra-violet rays it became "activated" and produced as good growth and calcification of bone as if the animal itself had been irradiated, hence radiation of the child's food will tend to promote bone calcification. This is, of course, the counsel of perfection, and, at the present time, not practicable for the many, but it would certainly make for the prevention of rickets.

Prophylactic Light Treatment.

Coming now to the child who has not had these advantages derived from his mother, it has been recently suggested by Mellanby that the anti-rachitic vitamins in food are increased, or made more active, by exposure to ultra-violet radiations, and that these tend to conserve ingested calcium and phosphorus for the use of the growing organism. Another measure which would do much to eradicate this widespread disease of children would be the raying of every child for a month or six weeks during the first year of his life. Two or three times a week would be all that would be needed, and this would have far-reaching effect and produce results at which one can only hazard a guess, but which I venture to think would be comparable to the effect that vaccination has had upon small-pox. Fifty years ago one met in the streets on every hand eyes blinded by this scourge, and it seems to me that I can remember that one face in every ten or a dozen was pock-marked. To-day such a thing is a rarity. But rickets, its results, and infant and child mortality, which can be traced to its malign influence, all take heavy toll, and, though the prevention of rickets by the light treatment of every child may appear extravagant at first sight, the paramount importance to the population of the prevention of rickets cannot be exaggerated. It is not only rickets as an entity which it is sought to extinguish, but, just as it is recognised that rachitic children are more liable to infectious and other diseases than the non-rickety children, so, with the prevention of rickets, the liability to many illnesses which contribute to child mortality is diminished. The prevention of rickets in the children of the nation is a national duty, and so surely as it is performed a national reward will follow in the bringing up of a population, few of whom will appear in class C 3, but who will be sturdier and stronger by the elimination of a disease which for too long has weakened and depleted the peoples of many races.

REPORTS ON
TUTOCAINE: A LOCAL ANÆSTHETIC.

I.—PHARMACOLOGY.

By E. WATSON-WILLIAMS, *M.C.*, Ch.M.,
CLINICAL LECTURER IN LARYNGOLOGY, UNIVERSITY OF BRISTOL.

Tutocaine is described as the hydrochloride of di-methyl-amino-methyl-p-aminobenzoyl-oxybutane, $C_{14}H_{22}O_2N_2 . HCl$; molecular weight 286·6, alkaloid content 87·3 per cent. As the formulæ below indicate, it is related to alypine and closely to stovaine. From the latter it differs (*a*) in the placing of the benzoyl nucleus, which is attached to the *third* carbon atom from that carrying the alkyl amino group (as in butyn); (*b*) in having an amino group attached to the benzene ring in the para position, in common with several anæsthetics derived from simpler paraffins.

Tutocaine is supplied as a faintly creamy-white powder, consisting of microscopic crystals. (Tablets and ampoules are said to be available.) This is soluble in cold distilled water up to 12 per cent., and more soluble in warm. The solution is neutral and optically inactive. It has a very faint yellowish tint, which darkens slightly on keeping. It can be boiled for a *short* time without decomposition, but should not be autoclaved (tutocaine appears rather less stable than cocaine hydrochloride when heated). Care should be taken to exclude all traces of alkali, which decomposes compounds of this type; some glass is alkaline! With ordinary care the solution will keep good for several days in a stoppered vessel. It grows moulds readily, and if dispensed in a corked bottle the addition of 1 part per 5000 of salicylic acid will be found useful—so prepared, the solution seems to remain active for at least three months. The taste is bitter, without special features.

If preferred, normal saline may be used to dissolve or dilute tutocaine. Adrenalin may be added; if so, this should be done immediately before use. Tutocaine is insoluble in oils. It is not subject to the Dangerous Drugs Acts. The price has not been fixed.

Experimental Toxicity.[1]

Compared to cocaine hydrochloride, the toxicity of 1 g. of tutocaine, estimated by the subcutaneous

---

[1] The expenses of the experimental work described below have been defrayed by a grant from the Colston Research Fund of the University of Bristol.

minimal lethal dose for guinea-pigs, gives the following values:—

Strength of solution ..	0·25 %	0·5 %	1 %	2 %	5 %	10 %
Tutocaine	—	5·9	7·1	7·9	8·3	8·6
Cocaine hydrochloride.	11	16	20	23	25	26

These figures indicate the weight of guinea-pigs in kilogrammes killed by 1 g. of the drug, and are the reciprocals of the minimal lethal doses in grammes per kilogramme.

Measured by this scale, tutocaine appears about three times less toxic than cocaine hydrochloride, and rather more than twice as toxic as novocaine. With convulsions as our criterion, the same proportion as regards cocaine is observed (which is uncommon). "Excitement" seems to be produced by doses much below the fatal dose, about 1/10 of the latter in guinea-pigs; tutocaine should therefore prove very safe to use in clinical practice, as ample warning should be afforded of any tendency to exceed a safe quantity. The same property indicates that tutocaine may prove useful to the drug-taker, who might be able to get the minor toxic effects that he seeks with little risk of serious poisoning. When death occurs it is from respiratory paralysis, the heart failing after the respiration ceases. One fatal accident (urological) with tutocaine has been published (vide below). The vertigo, head retraction, excitement, pupil dilation, convulsions, &c., seen in a guinea-pig poisoned with tutocaine resemble those seen with cocaine very closely—more so than do the manifestations of any other substitute with which I have worked.

The cocaine efficiency ratio of a drug is obtained thus: The figure found for the anæsthetic efficiency, as compared with that of cocaine under similar conditions, is divided by the figure expressing the toxicity, as compared with that of cocaine. The latter is usually taken to be the toxicity deduced from the experimental minimal lethal dose, determined in suitable animals, by a method—e.g., subcutaneous injection—comparable with that employed in clinical application of the drugs. If we accept the value deduced below for the cocaine anæsthetic ratio of tutocaine—namely, 70 per cent., or 0·70 unit—and the value given above for the comparative experimental lethal toxicity (subcutaneous)—namely, one-third, or 0·33 unit—we deduce a value for the cocaine efficiency ratio of tutocaine of 0·70 divided by 0·33, or 2·1.

No laboratory investigations of the local effects of tutocaine have been made for the purposes of this report, since the clinical evidence seemed so much more valuable. The drug has been extensively employed on the continent as a substitute for novocaine by injection. Our main purpose was to test the value of tutocaine for anæsthetising mucous membranes. And so, although it has been used in a few cases for major operations, and also for limited subcutaneous anæsthesia, with great success, attention has been concentrated on the other aspect. The clinical reports given below are based on upwards of 500 observations by six clinicians working independently, in an endeavour to explore the field where cocaine is generally used in this country (including dentistry).

My thanks are due to Prof. I. Walker Hall for permission to carry out the experimental work in the pathological laboratory of Bristol University; and to Messrs. Bayer Products, Ltd., for the supply of tutocaine used.

II.—RHINOLOGY.

By P. WATSON-WILLIAMS, M.D. Lond.,
CONSULTANT SURGEON FOR DISEASES OF THE EAR, NOSE, AND THROAT, BRISTOL ROYAL INFIRMARY, ETC.;
AND
E. WATSON-WILLIAMS.

Tutocaine has been used by us (independently) since the early summer of 1924; the following conclusions are based on over 200 observations. Of these, operations such as septal submucous resection, exploratory puncture of the antrum, removal of polypi, cauterisation, conchotomy, &c., furnished some 70.

Anæsthesia.—In nearly all the cases a 5 per cent. solution was applied by spray or tampon; a few minims sufficed for superficial work, and up to two fluid drachms have been used for more extensive operations. We have not injected the solution. In a few cases, among our earlier observations, the anæsthesia appeared less satisfactory than with 5 per cent. cocaine hydrochloride. It was found that this was due to the fact that tutocaine takes rather longer than cocaine of the same concentration to produce its full effect. For example, in a certain situation the average time for cocaine was 2 min. 5 sec., for tutocaine 2 min. 50 sec.; as we were applying for three minutes, cases occurred in which the effect of the tutocaine was incomplete. Since this has been recognised and allowance made, there has been no case in which good anæsthesia failed. Nine operations were performed on subjects of "neurasthenia" selected as unfavourable patients, with complete success. From a consideration of the various findings, including the time factor, we came to the conclusion that a 5 per cent. solution of tutocaine gave the same results as a 3·5 per cent. solution of cocaine—that, in fact, weight for weight, the anæsthetic efficiency of tutocaine was 70 per cent. that of cocaine hydrochloride when applied to the nasal mucosa. The duration of anæsthesia (with adrenalin) was about 45 minutes in a few cases in which it was tested. Some observations were made with 10 per cent. tutocaine; the results agreed with our previous findings.

Shrinkage.—Special attention was directed to this point. We have come to the conclusion that tutocaine does possess some power of producing shrinkage in the nose. As compared with that of cocaine, it was considerably less (in most cases) and took longer to develop; even when complete, a further shrinkage can be produced by cocaine. Also, there seemed no effect in arresting hæmorrhage; for operative work the addition of adrenalin (1/10,000) was necessary, and perfectly satisfactory. It seems probable that two factors are concerned in regulating the width of the nasal passages: (*a*) the vascular engorgement or otherwise of the nasal mucous membrane; (*b*) the expansion or contraction of the erectile tissue of the turbinals. (*a*) Does not seem to be affected by tutocaine; a slight initial pallor occurs but is transient—the same can be produced by a spray of cold normal saline. (*b*) Seems to be definitely influenced by tutocaine, though more slowly than it is by cocaine. Those cases show most "shrinkage" in which the turbinals are most swollen.

Irritation.—No cases of primary irritation were seen. In a few of the rare cases where cocaine solution produces late irritation, tutocaine did not act in this way. One patient showed the difference especially well, and greatly preferred tutocaine.

Dr. Z., a colleague, aged 70, who required periodical inflation of the ears by Eustachian catheter. He always found that for 24 hours after the use of cocaine his nose ran to an extent sufficient to cause him great inconvenience. After tutocaine this did not occur (several observations).

Toxicity.—No case showed either local or general signs of any toxic effect. In three cases, selected because cocaine had previously caused disturbance, tutocaine did not do so.

Case 402.—Female, 28. Had had nasal polypi removed three times under cocaine anæsthesia and had fainted after each operation. A polypus was removed under tutocaine without any disturbance; she was considerably surprised, for not knowing that cocaine had not been used she was expecting to faint this time too.

III.—OPHTHALMOLOGY.

By E. R. CHAMBERS, F.R.C.S. Edin.,
OPHTHALMIC SURGEON, BRISTOL ROYAL INFIRMARY;
AND
G. C. DIXON, F.R.C.S. Edin.,
RESIDENT MEDICAL OFFICER, BRISTOL EYE HOSPITAL.

We have used tutocaine in about 100 cases. Fresh solution is advisable, the addition of salicylic acid proving too irritating.

Anæsthesia.—For superficial work a 1 per cent. solution proved satisfactory. Onset of anæsthesia is somewhat later than with 2 per cent. cocaine (our usual preparation), but the degree of anæsthesia ultimately obtained is the same. For deep anæsthesia a 5 per cent. solution was used; this appeared to produce an effect almost exactly the same as that given by 4 per cent. cocaine. The loss of sensation was in every case good, and the duration of anæsthesia was always sufficient for our purpose; but no special tests were employed to determine the latter.

Irritation.—The weaker solution (without preservative) is quite unirritating. The stronger is perhaps slightly irritating, but very little more than cocaine. No case of late irritation or damage to the epithelium was observed. On application there is definite injection of the conjunctiva; the addition of weak adrenalin controls this. Some drying of the cornea tends to occur, but this is less than that found with cocaine.

Pupil Changes.—The pupil is dilated by tutocaine. This occurs much more slowly than with cocaine, and is of less extent.

Toxicity.—No evidence was obtained of any toxic effect.

IV.—UROLOGY.

By S. HARDY KINGSTON, M.B.,
Ch.B. Bristol, D.P.H.,
DERMATOLOGIST, BRISTOL ROYAL INFIRMARY.

Tutocaine has been used for the anæsthetising of the urethra in upwards of 50 cases of chronic gonorrhœa, &c. A 1 per cent. solution, without adrenalin, was found suitable, and of this 10–20 minims were used for each examination.

Anæsthesia.—This came on within three minutes, and lasted on the average 15 minutes. It was in every case quite satisfactory. For diagnostic purposes it allowed clear view of such things as congested patches, ecchymoses, or submucous infiltrations of the mucous membrane. For therapeutic purposes the anæsthesia allowed treatment of the lesions with astonishing precision and efficiency, and was most useful in the therapy of chronic urethritis. Those patients who had previously been treated under novocaine (2 per cent.) assured me of their marked preference for the complete anæsthesia produced by tutocaine. In no case did this fail.

Irritation.—No case of primary or late irritation occurred.

Ischæmia.—Neither ischæmia nor injection was observed. The solution was used without adrenalin.

Toxicity.—No evidence was obtained of any toxic effect.

One fatal accident with tutocaine used for urethral anæsthesia has been published (O. A. Schwarz). A man of 20, apparently physically strong, but somewhat puffy, and psychically not quite normal, complained of asthma and kidney pains. For the purpose of cystoscopy, 8 c.cm. of 2 per cent. tutocaine was applied to the urethra without adrenalin. Ten minutes later a violent fit occurred, with pupil dilation and biting of tongue. Then complete relaxation and "sleep." After a further 15 minutes another fit occurred. Again ten minutes unconsciousness, then clonic convulsions, respiratory embarrassment, cyanosis. Death occurred after 40 minutes from the application. Treatment had consisted in a caffein injection at the onset of symptoms. Autopsy: Status lymphaticus, thymus weighing 20 g. Death was undoubtedly due to poisoning. Schwarz considers that owing to the status lymphaticus, a dose which had always been harmless in others proved fatal in this case.

V.—DENTAL SURGERY.

BY L. E. CLAREMONT, M.R.C.S., L.R.C.P., L.D.S.,
SENIOR DENTAL SURGEON, BRISTOL GENERAL HOSPITAL, ETC.

FOR dental anæsthesia I have been using tutocaine in 0·5 per cent. solution without adrenalin. Up to 1·5 c.cm. of this has been employed at one time, the usual injection for a single tooth not exceeding 1 c.cm. Anæsthesia comes on within a few seconds; but for deep anæsthesia one must allow an interval of two minutes for the maxillary teeth, and five for the mandibular. The duration of anæsthesia is 20 minutes when the drug is used thus. In every case complete anæsthesia was obtained.

Side Effects.—No irritation or pain is caused on injection. In one case only was there some after-pain; this was in a case with exostosis of the roots, and it seems probable that the necessary forcible manipulation of the forceps might explain the late pain. No case occurred in which healing was delayed, or in which excessive bleeding was seen. No case showed any toxic symptoms. The results so far obtained are very encouraging.

A NEW OUTFIT FOR OXYGEN ADMINISTRATION.

BY H. WHITRIDGE DAVIES, M.B., B.S. ADELAIDE,
AND
A. RAE GILCHRIST, M.B., CH.B. EDIN.
(*From the Department of Therapeutics, University of Edinburgh.*)

EVER since its discovery by Lavoisier and by Priestley oxygen has been used for therapeutic purposes. The results, however, have been so disappointing that many clinicians have been disposed to dispense with it as useless. During and since the war, owing to intensive study of anoxæmia in aviators and in gassed men, and to the introduction of efficient methods for oxygen administration, most of the older misconceptions have been swept away and the gas has attained an assured place as a valuable and life-saving therapeutic agent. In this connexion the greatest credit is due to J. S. Haldane.

Indications for Oxygen.

Prompt and efficient oxygen administration is urgently demanded in all cases where the arterial blood leaving the lungs is deficient in oxygen saturation. This occurs in conditions where there is a lowered oxygen percentage or pressure in the inspired air and where, through bronchial obstruction or pulmonary lesions, the gaseous exchanges in the lungs are impaired. The most frequent pulmonary causes of anoxæmia are pneumonia and pulmonary œdema, and in the former it has been amply demonstrated by Meakins[1] that by efficient oxygen therapy it is possible to restore the arterial oxygen saturation to a normal level. Where the tissues lack oxygen owing to circulatory impairment the benefits from oxygen administration are less marked.

Apparatus for Administration.

Considerable need still exists for a simple, cheap, but efficient outfit for oxygen administration. The "tube-and-funnel" method as generally used is absolutely useless. Unless the funnel touches nose and chin and the gas is delivered at a very fast rate (not less than six litres per minute) little or no benefit can possibly be derived. The nasal tube method as described by Bourne[2] is little better except in infants. In both of these methods all the oxygen passing during the expiratory phase of respiration is entirely wasted.

The Haldane apparatus[3] gives excellent results in all but the severest degrees of oxygen-want. It gives an intermittent flow of oxygen, the gas being conserved during expiration, and for rates of oxygen flow of not more than half the subject's respiratory minute volume no better apparatus could be devised.

Our own outfit is essentially a modification of the Haldane apparatus. We have added to the latter a flow meter and a different type of valve, which provides in addition a means of moistening and warming the oxygen and of observing the flow of the gas. To the mask we have added an expiratory valve and an orifice of variable size for the admission of extra air. As an alternative to the mask we have introduced a forked nasal tube which can be used without loss of efficiency when the flow of oxygen is not more than a third of the respiratory minute volume. The general arrangement of the apparatus is shown diagrammatically in the figure. It consists of three parts: (1) cylinder and cylinder head attachment; (2) box containing flow meter, bag, and valve; (3) mask, and as an alternative a nasal tube.

The cylinder (A) may be of any suitable size, and the cylinder head attachment consists of a pressure gauge (B), a reducing valve (C), and a flow regulator (D). Oxygen is led through the flexible tube (E) to a box which can be hung on the back of the patient's bed. This box contains a flow meter (F), which indicates the rate of oxygen flow in litres per minute. From the flow meter oxygen passes to a bag (G) of about six litres capacity. During inspiration oxygen is drawn from the bag along the tube (H) through the wash bottle (I), which also acts as a valve. The bottle stands in an outer glass vessel (J), which can be filled with hot water. The box also contains compartments for storing the mask, nasal tubes, and cylinder head attachment. The tubes leading the oxygen from the bag (G) are of wide bore ($\frac{1}{2}$ inch) in order to allow of a free flow of oxygen. From (I) the oxygen passes along the tube (K) to a mask (L) or nasal tube (O). The mask is fitted with the usual pneumatic face-pad, and is attached by means of a broad band of elastic webbing. On the front of the mask are placed an expiratory valve (N) and an extra air orifice (M), which may be closed completely or opened to any desired extent. The forked nasal tube has two prongs, one of which is inserted into each nostril. It is held in position by an elastic forehead band. This has been devised as a useful alternative to the mask for patients in whom there is no nasal obstruction or who are unable to tolerate a mask. Where continuous oxygen therapy is indicated it affords a welcome change, for after an hour or so a mask may become somewhat annoying to the patient.

Method of Use.

The apparatus is used as follows. The cylinder head valve is freely opened and the regulating valve (D) so adjusted as to give an oxygen flow of 10 to 12 litres per minute. The extra air orifice (M) on the mask is completely closed, and when the bag (G) is moderately well filled the mask is applied to the patient's face. The patient is now breathing pure oxygen, and the rate of flow should be so adapted as exactly to equal his respiratory minute volume. This is done by observing the bag and the wash bottle. If the bag tends to empty itself completely the oxygen flow should be increased. If, on the other hand, the bag tends to overfill, and the bubbling through the valve to become continuous, the flow should be diminished. After a little adjustment a mean is attained in which the bag neither over-fills nor completely empties, and the oxygen bubbles through only during inspiration. A reading of the flow meter at this point gives approximately the patient's minute volume of respiration which should be carefully noted. When this has been done the flow of oxygen is cut down to the amount slightly more than that sufficient to keep cyanosis in abeyance, the extra air orifice being opened to a sufficient degree. If the extra air orifice is too widely opened the oxygen will tend to accumulate in the bag until it over-fills, and the oxygen will then pass in a slow and almost continuous stream. If insufficient extra air be allowed the bag will be sucked empty and the subject will then have to make an appreciable effort in order to obtain enough room air to complete each inspiratory act. The apparatus thus enables the physician to determine approximately the patient's respiratory minute volume and to adapt the oxygen flow to it. From the ratio between the two it is possible to calculate approximately the oxygen percentage in the alveolar air provided that no oxygen bubbles through the water valve during expiration, and that no leakage is present between the mask and the patient's face. Thus when the oxygen flow is equal to or greater than the respiratory minute volume and no extra air is admitted, the patient will be breathing pure oxygen, and the percentage of the gas in the alveolar air is approximately 94. When the oxygen flow is 2/3 of the respiratory minute volume the alveolar oxygen percentage is approximately 67. A ratio 1 : 2 gives 54 per cent. of oxygen in the alveolar air, 1 : 3 gives 41 per cent., and 1 : 4 gives 34 per cent. The alveolar oxygen percentage necessary to abolish the symptoms of anoxæmia affords an approximate quantitative index of the severity and extent of the pulmonary lesion.

---

[1] Meakins: Jour. of Path. and Bact., 1921, xxiv., 79.

[2] Bourne: THE LANCET, 1922, ii., 23.

[3] Haldane: Respiration, New Haven, 1922, p. 152.

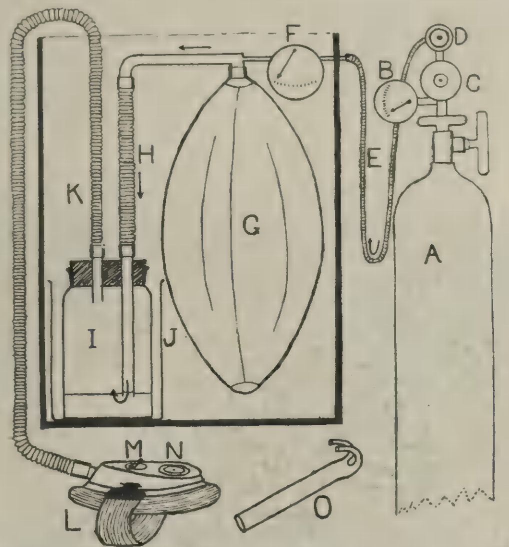

Diagram to show general arrangement of apparatus. (An explanation of the letters is given in the text.)

We have made careful comparisons of the different methods of oxygen administration, and have found that the above method shows a high degree of efficiency at all ratios of oxygen flow to respiratory minute volume. We have found that the tube and funnel and nasal catheter methods are of little value and extremely wasteful. The Haldane method is highly efficient at low rates of oxygen flow, but wastes oxygen when the flow is more than half the respiratory minute volume. A full account of all this work is published elsewhere.[4] The apparatus described above is made by Messrs. Siebe Gorman and Co., Ltd., 187, Westminster Bridge-road, London. If so desired the tube (E) can be led to the box from a suitable liquid oxygen vaporiser instead of from the cylinder as depicted in our diagram.

Conclusion.

In conclusion we would plead for the more extensive use of oxygen in an *efficient* and *quantitative* manner, particularly in pneumonia and especially in the early stages of the disease. If anoxæmia be left unrelieved for more than a very few hours the results of oxygen therapy are frequently disappointing. Cyanosis should be forestalled, or at any rate abolished, by oxygen administration as soon as it becomes apparent. We have considerable clinical evidence that if this were done the mortality from pneumonia could be reduced, the severity of the symptoms markedly lessened, and a speedier termination of the infectious process assured.

We wish to express our indebtedness to Prof. Murray Lyon for his helpful criticism and advice in connexion with the preparation of this paper.

Clinical and Laboratory Notes.

TWO CASES OF DIPHTHERIA WITH UNCOMMON COMPLICATIONS.

By J. TODESCO, M.D. FLORENCE, M.R.C.S., D.P.H. LOND.,
RESIDENT MEDICAL SUPERINTENDENT, CROYDON BOROUGH HOSPITAL.

IN the following two fatal cases of diphtheria the unusual nature of the complications renders them worthy of record.

CASE 1.—A woman, aged 50, unmarried, was admitted to hospital on Feb. 3rd, 1924, suffering from acute diphtheria affecting the nose and throat. She had been ill for two days. There was extensive ulceration of the throat, with sloughing membrane extending into the mouth, profuse purulent rhinorrhœa, the glands of the neck were exceedingly large and tender, with some difficulty of swallowing, and signs of acute bronchitis with much expectoration. The heart's action was regular with weak sounds. Temp. 101° F., pulse 120. Swabs from nose and throat showed many diphtheria bacilli. The throat conditions did not clear up readily, and the glands remained enlarged. On Feb. 13th the voice became nasal, the left side of palate was paralysed, with a perforation of palate on one side. There was some regurgitation of fluids, and, owing to increasing difficulty of swallowing, all feeding by mouth was stopped.

On March 10th patient vomited greenish fluid after a nasal feed. There appeared to be much post-nasal secretion, excessive salivation, and difficulty of expectoration, the palatal paralysis persisting. On the 14th the tongue, when protruded, was deflected to the left side, whilst the lower lip was drawn over to the right, her speech being very indistinct. On testing the lower limbs, the reflexes were absent, but there were no sensory or motor changes. Four days later the patient suddenly became very cyanosed and dyspnœic and vomited greenish fluid several times. Her pulse-rate increased rapidly to 160 ; it was small and weak ; the temperature 100·2°. Signs of acute bronchitis were more marked, and she could not expectorate, though there was much secretion and excessive salivation. The paralysis of facial, twelfth, and vagus on left side was still apparent. From this time on her condition became worse. She appeared very distressed, and the pulse remained persistently weak and rapid. Death occurred suddenly on March 21st.

CASE 2.—A girl, aged 16, was admitted to hospital on Dec. 4th, 1924, with a history of sore-throat and shivering which had started six days previously. On examination she was flushed, had a " bull neck," and marked œdema of both upper and lower eyelids, so that the eyes could not be opened, and profuse semi-purulent discharge from both. The face was generally swollen, as well as the upper lip. There was profuse blood-stained rhinorrhœa with incrustation of nostrils which were blocked with membrane. Throat examination proved difficult, as the mouth could not be easily opened. The fauces were very swollen and congested, with œdema of the posterior part of tongue and marked ulceration of palate. Sloughing membrane covered the whole of the pharynx and extended forward into the buccal cavity. On Dec. 15th the œdema of eyelids was less marked so that the eyes could be opened slightly; the discharge was more watery and straw-coloured. Both pupils were equal, reacting to light, and vision was normal. A culture taken on admission from throat, nose, and eyes was positive for diphtheria in each case. On the following day the œdema of eyelids had practically disappeared, the discharge ceased, but there was marked ecchymosis affecting eyelids, and extending down to malar bones and over the bridge of nose and forehead. Patient now showed signs of heart failure, and was cyanosed and restless at times. She felt cold and clammy, the heart's action being weak and irregular. She died suddenly on Dec. 17th. The temperature throughout ranged between 99° and 101° and towards the end many petechial spots were apparent on chest, neck, and limbs.

Commentary.

These two cases are interesting owing to the uncommon nature of their complications. As regards the first, paralysis of the hypoglossal nerve is extremely rare in diphtheria. It came on five weeks after the onset of disease, whilst the palatal paralysis started on the thirteenth day. The facial palsy was incomplete, apparently only affecting the mouth. As regards the second case, the eye condition was probably an instance of the interstitial form of conjunctivitis described by the late Dr. Claude Ker, in which, in addition to much œdema of the lids, there is profuse straw-coloured discharge. It is remarkable that in spite of the acute nature of the condition the corneæ were clear and vision was normal. Lastly, it is interesting to note that the eye swab culture gave a positive virulence test, proving that the eye condition was due to a virulent diphtheria organism and not a diphtheroid.

I am indebted to Dr. H. P. Newsholme, medical officer of health for Croydon, for permission to publish these cases.

A CASE OF TRUE DEXTROCARDIA.

BY NORMAN B. CAPON, M.D.LIVERP., M.R.C.P.LOND.,
HON. ASSISTANT PHYSICIAN, ROYAL SOUTHERN HOSPITAL, LIVERPOOL;
AND
E. NOBLE CHAMBERLAIN, M.D. LIVERP., M.R.C.P. LOND.,
HON. MEDICAL OFFICER, CARDIOGRAPHIC DEPARTMENT OF THE HOSPITAL.

INSTANCES of dextrocardia without transposition of other viscera are so rare as to warrant the publication of the following case.

The patient, a female child, aged 26 months, was admitted to the Royal Southern Hospital on Nov. 15th, 1923. She had recently been treated for broncho-pneumonia following whooping-cough.

On admission she was found to be seriously emaciated; temperature 102° F., pulse and respirations 148 and 54 respectively. The base of the left lung was very dull to percussion; inspiratory crepitations were audible over the same area, and the heart was displaced to the right. The left pleural cavity was explored with a needle on the day of admission, and again two days later. On neither occasion was fluid withdrawn. The temperature followed an irregular, intermittent course.

On the fourth day after admission the apex of the left upper lobe was also found to be dull to percussion; vocal resonance was increased and the breath sounds were bronchial in character. Over the right lung the percussion note was hyper-resonant.

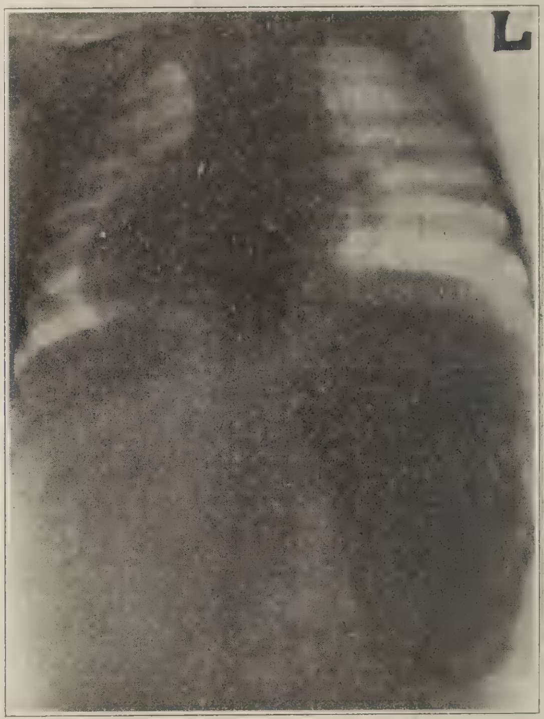
Gradual improvement, with resolution of the pneumonic zones, took place. Finally, only a chronic bronchitis of moderate degree remained, but the heart did not return from its abnormal position.

The child was sent away for convalescence to the Heswall Branch of the Royal Liverpool Children's Hospital, where she improved greatly under the care of Dr. C. J. Macalister. Later she was readmitted to the Royal Southern Hospital for further observation.

Her present condition is as follows: The patient is well-nourished and is rapidly developing, though she is still backward for her age. The lungs show no abnormal physical signs except those of residual chronic bronchitis. The apex-beat of the heart can be felt to the right of the mid-line, and the deep cardiac dullness extends 2¼ inches from the midsternal line in the fifth intercostal space of the right side. The cardiac rhythm is normal, and the heart sounds almost equal in duration and intensity; they are loudest at the apex-beat, where a short systolic bruit is audible from time to time. This murmur does not resemble a bruit due to congenital cardiac malformation. The systolic blood pressure is 70 mm. Hg. The liver is palpable on the right side of the abdomen. There are no physical signs of any deformities other than those stated above. Radiographic examination (see Fig. 1) confirms the dextrocardia and reveals a normally placed stomach and liver. There is no X ray evidence of delayed ossification of the bones of the hands.

Using the customary leads, the electrocardiogram shows inversion of P.R.T. in leads I. and II., with normal deflections in lead III. (see Fig. 2). If the leads from the right arm and left arm are interchanged, the resulting curves show normal deflections in leads I. and II., with inversion of all waves in lead III. (see Fig. 3).

FIG. 1.



Right-sided heart. The stomach, distended with bismuth meal, lies on the left side of the body.

Comments.

The following are important features of this case. First, the displacement of the heart to the right, together with signs of pneumonia in the left lung, pointed very suggestively, though wrongly, to the presence of fluid in the left pleural cavity. Second, the patient is an example of the very rare condition of true dextrocardia without transposition of the abdominal viscera. We can find only two cases published with electrocardiographic evidence—namely, those of Moffett and Neuhof,[1] and of Meyer.[2] Third, there is difficulty in explaining the inversion of P.R.T. in lead II. Willius[3] records a similar finding in a case of dextrocardia, and attributes the inversion in lead II. to "an exaggeration of the inclination of the cardiac axis to the right."

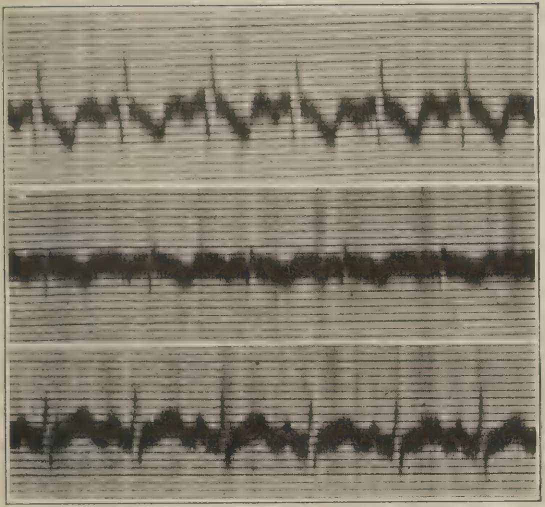
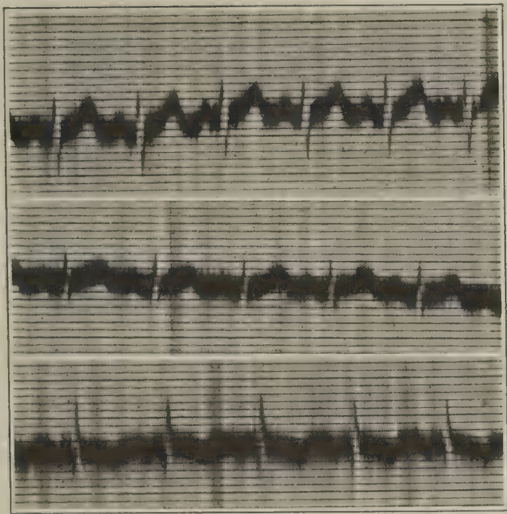
Sir Thomas Lewis has very kindly examined our electrocardiograms, and considers that the inversion of all waves in lead I. is due to true dextrocardia, but that the inversions in lead II. are due to bizarre deflections which are so often found in lead III. of apparently normal subjects; for, as he has pointed out,[4] lead II. of an individual with dextrocardia corresponds with lead III. of a normal person.

Fig. 2.



Inversion of all waves in leads I. and II.

Fig. 3.



Electrocardiogram taken with the right arm and left arm leads reversed. Inversion of P.R.T. in lead III. only.

In conclusion, we wish to thank Prof. John Hay for examining this patient with us, and for giving us the benefit of his valuable advice, and Dr. J. H. Mather for the radiographs.

Medical Societies.

BRITISH CONGRESS OF OBSTETRICS AND GYNÆCOLOGY.

Puerperal Sepsis.

On April 22nd and the two following days the Congress held a session at the rooms of the Royal Society of Medicine, under the presidency of Dr. H. Russell Andrews. On the morning of Wednesday reports on the prognosis and treatment of puerperal sepsis, by a committee of the Section of the Royal Society of Medicine and by a committee of the North of England Obstetrical and Gynæcological Society, were submitted. Sir Ewen Maclean read a paper on puerperal sepsis in Wales, Dr. G. FitzGibbon and Dr. J. W. Bigger submitted one on a clinical and bacteriological investigation of puerperal fever, and Dr. L. P. Lockhart spoke on bacteriological examinations during pregnancy. Sir Ewen Maclean's elaborate paper showed that Wales had a consistently high maternal mortality rate, higher than the combined figures for England and Wales. For England and Wales as a whole the death-rate from sepsis was lowest in rural districts and became higher as the urbanisation of the population increased. On the other hand, the "other causes" of death showed the opposite tendency—i.e., lowest in the urban districts. There was agreement as to the need in Wales of a larger supply of qualified midwives, more equably distributed.

The general discussion on the subject in the afternoon was opened by Prof. J. Whitridge Williams, of Baltimore University, U.S.A. The chair was occupied by Dr. J. E. Gemmell.

Prof. Williams said that as the London report showed a mortality of 35·8 per cent. in these cases, and the North of England report gave 76 per cent. mortality, it was clear that the latter included much more serious cases than the former. Adding the cases together they showed that 403 cases were treated, with a net mortality of 48 per cent.—i.e., one patient in every two with the condition died from it, a reasonably good result if they were all frank cases of the disease. Both reports brought out the facts that women who had been subjected to much manipulation and women who had had hæmorrhage were much more liable to infection than were others, though a certain number on whom there had not been manipulation died nevertheless. That it was a contact infection everyone now believed, and it would be a misfortune if that view were abandoned. A rapid pulse meant an ominous prognosis, and the higher and the more prolonged the temperature the more serious was the outlook. It was necessary to realise that there were two types of cases: one which would get well if left alone, another which would die whatever might be done. Both reports showed a mortality of some 80 per cent. in women who had been subjected to intra-uterine manipulations. He had taught for a long time that the worst thing that could be done was to interfere with the interior of an infected woman's uterus.

There was a marked difference in the two reports in the matter of the results following the use of anti-streptococcic serum. The London Committee stated that 33 cases were so treated with a mortality of 18 per cent., and in the North of England 104 cases, showing a mortality of 72 per cent. When one encountered a severe case of puerperal infection, anti-streptococcus serum seemed to be of no avail. Therefore all that could be done was to try to find some means of combating it. Two-thirds of patients with the thrombo-phlebitic form of pyæmia would die if left alone, and if operated upon they would probably all die. The less severe cases which did not come into these categories would recover if left alone, because the outcome depended on the degree of resistance of the patient and on the virulence of the causative bacteria. Vigorous measures applied to these milder forms might convert a condition which was likely to be recovered from into one which might be fatal. There was need of research, not purely obstetrical, but along the general lines of bacteriotoxic methods.

Dealing with the communication of Dr. FitzGibbon and Dr. Bigger, in which they said they found streptococci in the vagina of two out of every three pregnant women, and in half the cases of puerperal conditions, and that the non-hæmolytic form was probably endogenous in origin, he said he did not think any technique employing a speculum for obtaining vaginal secretions was above suspicion. In ordinary women he did not think there were streptococci of any kind in these regions. Except in the cases of the gonococcus and certain saprophytic organisms, he thought it was a misfortune to talk about endogenous infection. To the end of December, 1924, out of 3000 consecutive admissions in his clinic there were 436 cases of rise of temperature in which it was necessary to consider the possibility of intra-uterine infection; 353 of them were puerperal infections—i.e., 11·7 per cent. Cultures were taken with the following results: *Streptococcus hæmolyticus* 32, non-hæmolytic 34, colon bacillus 13, gonococcus 23, staphylococcus 7, saprophytes 96, while 23 were sterile. This series did not include women who were brought after infection had occurred. In the series there were three deaths, and two of the women who died were brought after infection had occurred and were in labour; hence the responsibility for their death did not fall on the clinic. But one woman died who had hæmolytic streptococcus, whose vagina had not been examined, who had a spontaneous labour, and no perineal tear. In many of the cases which some would regard as endogenous in origin the women examined themselves, doubtless with dirty hands, and in some there was a history that there had been coitus during labour.

Prof. Blair Bell said that cases having a sudden onset of septicæmia and very little local resistance practically all died. But he did not agree with Prof. Whitridge Williams's passive attitude in these serious cases, as he, the speaker, thought there was a chance, chiefly with the aid of surgery, of saving their lives. Recently, in a patient who had general streptococcal peritonitis due to the hæmolyticus, also bronchopneumonia, all the treatment adopted was to drain the fluid from the abdominal cavity and treat her in the open air, and she recovered. It was only by starting investigations at the very beginning that light could be gained, especially in the prevention of the condition under discussion. Thousands of cases should be examined bacteriologically and their histories followed up. It had always been his view that coitus shortly before full time was a likely means of introducing streptococci into the vagina. Twenty per cent. of the cases in which this history was given showed the *Strept. hæmolyticus*. Digital examination before patients were admitted acted in a similar way.

Mr. Victor Bonney argued that quite a large number of these cases were due to an endogenous cause—i.e., were auto-genetic. Despite the increasing attention paid to sources of outside infection and the assiduity of the teaching there had been very little fall in puerperal morbidity due to sepsis. It was at least significant that in 200 cases in one report the origin of the sepsis was not stated; he would have liked to see the compilers show a little more boldness and attribute them to intrinsic sepsis. At Chelsea Hospital, in 1900, the mortality for major abdominal operations was 5 to 6 per cent. In 1906 it had fallen to 1·6 per cent., and had since remained at about the same figure. The improvement synchronised with the use of gloves at operations; nothing else was changed; the personnel of the staff and the technique remained the same. Obviously those measures would not operate against intrinsic infection. Streptococcal vaginitis he considered to be very common, and in women in whom that was established it was a source of real danger.

Prof. H. Briggs said it was necessary to know what temperature constituted the onset of this condition. If the pyrexial period was taken as 24 hours after labour, was not the opportunity lost of producing a number of premature labours among these women? He thought the outcome of the discussion was that until in London there was a clinical equipment similar to that of the Rotunda in Dublin, with a 1·1 per 1000 mortality in septicæmia, there would not be any very great improvement.

Prof. Beckwith Whitehouse said he had learned two points of importance from the discussion: that puerperal sepsis depended largely upon two factors. The first was the amount of damage which had been done to the tissues; the second, the amount of hæmorrhage which had already occurred. Damage invited infection, hæmorrhage lowered the patient's resistance. Fifty of his cases were examined bacteriologically, and in only five of them were hæmolytic streptococci found in the cervix, and the patients went through a normal labour and puerperium. In only 12 of 500 cases did the temperature rise to conform to the standard laid down by the British Medical Association, and those 12 included a certain number of forceps deliveries. He asked whether it would not be possible, in the interests of the nation, to ensure that every woman should be examined at least in the eighth month of her pregnancy and have the combined attention of doctor and midwife. The latter could not be expected always to recognise abnormalities when they were present. He agreed with what had been said as to coitus as a factor in puerperal sepsis, and mentioned a case in which a husband admitted coitus within a fortnight of his wife's delivery.

Dr. F. J. McCann preferred the term puerperal genital infection, comparable to ordinary wound infection in general surgery. The main hope in treatment was antenatal care, for the subject was closely related to the housing question, as women could not be expected to give birth to a child in dirty and inadequate surroundings without becoming infected. Notification had proved a failure, and if it was to continue provision must be made for the sufferers in hospital. It was a blot that these women were admitted into fever hospitals. A badly infected case should never be left; the gynæcologist should stick to it to the last. In intense and foul toxæmia he found starvation of great value; it brought about a localisation of the pus, so that it could be drained away.

Dr. B. Dawson (South Australia) said that Australia showed a higher mortality from causes associated with parturition than that of Great Britain; in 1922 the figure for the colony was 4·7 per 1000, as against Britain's 3·81. The death-rate from septic conditions was practically the same in both countries. In Australia there was nothing corresponding with Britain's Central Midwives Board, and only during the last two years had registration of nurses been operative. Women living in outlying farms under pioneer conditions had to endure, in childbirth, more than could well be imagined. In Australia there was a growing demand among the public for supervision during pregnancy. He made a plea, by request of his colleagues, for an Imperial, possibly an international, system whereby cases might be recorded on a uniform sheet, a standard means of case record. He also suggested that the bacteriological technique should be standardised, and that in certain well-defined clinical conditions the treatment should be uniform and should be revised and so controlled at periodic dates.

Dr. Remington Hobbs said that a uterus in a state of sepsis was a contra-indication for exploration of its cavity. But it should be exposed to view in every case, and any products seen should be twisted off. Speaking of a series of 7000 cases of septic uterus, he said exploration was done only when there was severe hæmorrhage. He had frequently known a rise of temperature follow curetting and swabbing out with strong antiseptics, and after quite hot intra-uterine irrigation. He had found that glycerine produced osmosis of the tissues, drained the cavity as well as the cervical canal, and greatly assisted involution of the uterus. It should be recognised that in this condition the uterus needed many treatments. If the uterus were drained the need would not arise to remove so many Fallopian tubes.

Colonel L. W. **Harrison** reminded the Congress that Dr. T. H. C. Stevenson had pointed out the high incidence of puerperal mortality about nine months after the peak of the demobilisation curve. Dr. Stevenson asked the speaker whether there was likely to be any connexion between that fact and venereal infection. He suggested that the reason might be that large numbers of men infected their wives with gonorrhœa when they were demobilised, and that this disease was succeeded by a mixed infection of streptococci and staphylococci. He was sure many cases of so-called chronic gonorrhœa were those from which the gonococcus had long since disappeared and had been replaced by other micro-organisms, which would not have gained a footing but for the soil having been prepared for them by the gonococcal infection. Colonel Harrison gave reasons for believing that ophthalmia neonatorum was more likely to occur in the offspring if the infection of the woman occurred somewhat late in her gestation; whereas if she were infected early in the pregnancy, puerperal fever was the more likely sequel. As gonorrhœa was a mild disease in women compared with that in men, it was a good deal neglected in the former.

Dr. W. P. P. **Gordon** said that New Zealand had the lowest infantile mortality in the world and one of the highest maternal mortalities, and he asked whether the maternal statistics published were reliable as a guide to incidence rate of puerperal sepsis. In New Zealand puerperal morbidity had to be notified—i.e., every patient in hospital who had a temperature of over 100° F. for more than two days.

Dr. **James Hendry** spoke of cases in Paisley in which pyrexia did not occur until after birth. For all cases there was a morbidity incidence of 3 per cent. in the hospital.

Dr. C. E. **Douglas** said that in his general practice of 44 years he had had 2200 cases and had operated on 557. He applied forceps in the second stage of labour whenever he thought it proper to do so. He had had only one death from sepsis. His patients were from a very healthy agricultural district. The factor which had been very little considered was the woman herself. It was not safe to assume that the woman about to have a baby was a healthy person; she might have tubercle bacilli in her system which would only reveal themselves in pregnancy. And the pregnant woman showed various abnormalities in comparison with the non-pregnant.

Prof. M. H. **Phillips** gave his experience of these cases in the Monsall Hospital, Manchester, in which a block was set apart for puerperal fever cases. They had been treated by ordinary methods. Since the beginning of 1924, however, he had treated the cases of septic uterus by putting into the uterus glycerine, and the results had been very promising. Forty-five cases were so treated, and their average stay in hospital was 25·9 days, as compared with 39 days under treatment by rest, or by rest and sharp curettage. He exhibited comparative tables of his results.

Lady **Barrett** spoke of the investigation of a series of cases of morbidity occurring in hospital, from the point of view of the source of the sepsis, and the best way of ending the sepsis in each case. There were two separate outbreaks of infection, which seemed to have different causes. In one it seemed to be due to the accoucheur, who had severe oral sepsis. Cases delivered by that person who were not on the morbidity list also showed some rise of temperature, but not up to 100° F. Probably their own resistance was effective against the infection. In the second series there seemed to have been nothing in common, except that each, during the first few days, had been in the same position in a particular ward. When this movement was stopped and no further admissions were allowed until the ward had been fumigated, no further cases occurred. The speaker showed how different people exhibited a very varying response to similar circumstances.

Mr. A. W. **Bourne** said that the preventive aspect of the subject required that more bacteriological and serological work should be done. Twenty-five per cent. of the cases mentioned in one of the reports had no apparent ætiological factor. With regard to the other 75 per cent. of cases, the great need seemed to be more efficient teaching. Students and the profession generally could not be too insistently taught the enormous importance of antenatal examination and treatment, and the necessity for only the minimum intranatal interference.

Dr. T. **Watts Eden** said the profession had scarcely yet begun the systematic study of puerperal infection; it had not even settled whether, for the most part, the infection was intrinsic or extrinsic. Nor was the real significance of streptococci in the vagina known. Until hospitals provided special accommodation for puerperal sepsis cases, so that they could be investigated from beginning to end, there would not be much progress in the matter. There must first be real assistance from the Government. On the suggestion of Dr. Fletcher Shaw, he proposed that a memorial be sent from this Congress to the Ministry of Health urging the provision of hospital accommodation for the care and investigation of these cases.

This proposal was unanimously agreed to.

At the Thursday morning session the chair was occupied by Prof. B. P. **Watson**.

Prolapsus Uteri.

Prof. W. W. **Chipman** (Montreal) read a paper, which was illustrated on the epidiascope, on prolapsus uteri, describing the operation now being done for the condition in Montreal. He said that though no one operation would suit all cases, this method had satisfactorily stood the test for ten years. The condition was really a sacro-pubic hernia through the fibrous diaphragm of the true pelvic floor; it was a sliding hernia. The operation he described consisted in exposure of the fascial cleft, the replacement of the viscera, and the radical cure of the hernia. He regarded the operation as anatomically sound, and it was a simple one.

Mr. R. H. **Paramore** said he had not met with the masses of fibro-muscular tissue in the pelvis which Prof. Chipman described. During the last five years he had been doing an operation on the muscle floor of the pelvis only, which he described, and mentioned three cases in which he had carried it out.

Dr. G. **Fletcher Shaw** said that if the perivascular tissue were thoroughly stitched in front of the cervix and a posterior colporrhaphy done there would be no fear of any recurrence. The operation was much more satisfactory when a good portion of the cervix was removed.

Dr. **Leith Murray** said that in Newcastle the cervix was amputated for this condition in child-bearing women.

Prof. **Munro Kerr** remarked that if the cervix were well dilated before doing amputation, stitching was rendered very much easier. The vagina should be thoroughly packed afterwards.

Mr. T. G. **Stevens** spoke of the secondary hæmorrhage which was sometimes encountered about the seventh to the tenth day, usually due to the cutting through of the suture which turned in the mucous membrane to the cervical canal.

Dr. **FitzGibbon** said one of the advantages of the operation was the conservation of vaginal mucous membrane, especially at the fornices. Unless there was marked hypertrophy of the cervix, it could usually be saved.

The After-Results of the Subperitoneal Gilliam Operation.

Dr. **Bethel Solomons** read a contribution on this subject. He said there were divergent views on the treatment of backward displacement, and many symptoms followed upon it. 176 replies had been received from patients on whom the operation had been done more than a year ago. Four were absolutely cured of sciatica which had been intractable. Of the 107 who had had backache, 101 had relief, 6 were not benefited at all. Some who had had dysmenorrhœa were cured of it by the operation. 67 of the women had since had children at full term; only 3 had since had miscarriages. The main indications for operation were backache, sterility, dysmenorrhœa, and frequent abortions. Full anæsthesia was necessary, otherwise the rigidity of the recti impeded the operation. He was very favourably impressed by the results.

Prof. A. Donald protested against these abdominal operations undertaken for retroversion, the frequency of which almost amounted to a scandal.

Prof. Watson spoke of the difficulty of diagnosing the cause of this condition. One of the commonest was cervical laceration. A pessary should be applied in doubtful cases. Every means should be taken to eliminate the uterus as a possible cause.

Dr. Wilfred Shaw read a paper on the relationship between ovulation, corpus luteum formation, and menstruation, and Prof. Munro Kerr one on a case of pseudomyxoma peritonei with affection of the appendix.

The chairman at the Thursday afternoon session was Prof. T. Wilson.

Premature Separation of the Placenta.

Prof. Whitridge Williams gave a contribution on this subject. He said that in 9000 admissions to his clinic there were 57 cases of premature separation of the placenta and 64 cases of placenta prævia. He discussed specially 40 cases, from 15 to 43 years of age. Twelve were primiparæ. In 19 of the 40 cases the condition was mild, in 21 it was severe. Ten cases required Cæsarean section. There were 3 maternal deaths, 29 fœtal deaths, all in the Cæsarean section cases. Inflammatory changes in the decidua could be excluded, and syphilis played no part; in 37 of the 40 cases the Wassermann was negative. He admitted he did not know the cause of the condition. It had been stated that albuminuria played a marked part, but 15 of these patients showed no sign of albuminuria, either before or after the accident. On two of the women who died post-mortem examinations were done, and no sign of toxæmia was found. He agreed with a French authority that in cases of premature separation no special significance should be attached to an increased pulse-rate.

Prof. Watson said he thought it would be agreed that the primary condition was hæmorrhage into the uterine wall, and the separation of the placenta was a mechanical result of that.

Treatment of Inoperable Carcinoma by Radium.

Papers on this subject were read by Dr. Malcolm Donaldson and by Dr. G. I. Strachan.

Dr. Donaldson said his object was to show the effect of radium treatment on the local condition. In the more recently treated cases with the longest duration of treatment, the growth disappeared in, on the average, five to six weeks, in the less advanced conditions the time taken for disappearance was even less. The method followed was to insert a number of needles (2 to 13) of 100 to 140 milligrammes of radium element, and the duration of application was eight hours. The results in these severe cases were such that it was important to have organised research on the subject. He pleaded for full reports of cases so treated, stating whether the actual salt or the gas emanation was used, the number of milligrammes, the applicators, and the time of application of the irradiation. He described his procedure in detail and exhibited full lists of his cases. In a general way, mild irradiation over a wide field for a long time he found best.

Dr. Strachan gave his results in 40 cases of carcinoma. In some the cervix had ceased to exist as a protrusion into the vault, and was represented by a bleeding ulcer, hence it was difficult to apply the radium. After the radium treatment there should be a douche every morning for three weeks, as it prevented the supervention of vaginitis. In the presence of vesicovaginal fistula, radium was inadmissible, as acute cystitis was apt to be set up. Six weeks after radium had been applied there was evidence of increased fibrosis, and 11 weeks afterwards most of the cells were entirely degenerated. The reaction of carcinoma of the cervix to radium was good, but that of carcinoma of the vagina to it was not so good. In epithelioma of the vulva the result of the application of radium was bad.

Albuminurias of Pregnancy in New Zealand.

Dr. Agnes Bennett read a paper entitled The Albuminurias of Pregnancy in the State Maternity Hospitals of New Zealand. It consisted of a plea for authoritative pronouncements on this subject for the guidance of all practitioners in the Empire, especially in the matter of treatment.

Toxæmias of Pregnancy.

Prof. Louise McIlroy read a contribution by herself and Dr. E. Pillman Williams on the toxæmias of pregnancy from their clinical and chemical aspects. The paper stated that the authors had not arrived at any definite explanation of the origin of the group of conditions dealt with, nor why one symptom or group of symptoms should declare themselves. In many it was difficult to say where physiological changes ended and pathological changes began. In many instances they considered that toxic conditions existed previous to the pregnancy, and that the chief sources of these toxins were in the intestine. The ovum was added to the toxic factory, and contributed its quota to the toxic state. In pregnancy there was an inability to cope with the toxins arising from defective excretion, coupled with toxins from the ovum, though the trophoblast was responsible for the generation of toxins rather than the fœtus. The main point was as to whether toxæmia was present, and if so, what was its severity? In many of the cases there was chronic intestinal stasis with distension of the colon over the region of the cæcum; in many there was a history of attacks of appendicitis. Toxæmia was more marked in primigravida than in multipara. There was a definite fall of nitrogen content in the blood throughout the whole gestation. Most of the cases of vomiting admitted to the wards showed signs of toxæmia; it was not a question of mere neurosis. Headache in some cases was found to be due to increased intracranial tension, and usually there were small rises in the blood-urea. If œdema occurred early in the pregnancy, the cause was to be found in deficient renal function. In cases which had vomiting, increased food gave better results than the induction of abortion. Only 3 of the 172 cases recorded had to have abortion induced; and in this series there was only one case of eclampsia.

At the concluding session on Friday morning the chair was occupied by Dr. Louis Cassidy.

Endometrioma.

Prof. A. Donald and Dr. K. V. Bailey submitted the results of a clinical and pathological study of endometrioma, bringing out the chief points by epidiascope demonstrations. 108 cases were passed in review. Of 55 cases there were 35 women who had had no pregnancy for seven years. The most important symptom was dysmenorrhœa, which was present in 70 per cent. It was acquired in 55 per cent. of these. Menorrhagia was present in 57 per cent., leucorrhœa in 38 per cent., and backache in 28 per cent. Pain on defæcation and other rectal troubles were complained of by some. Tarry cysts were found at operation in 77 per cent., and an adenomyoma in the recto-vaginal space in 63 per cent. A very important feature was that the rectum was adherent in 76 per cent., and there was need, the authors considered, for a careful investigation of the nature of the causal irritation.

The last contribution was a very elaborate one, supported by a wealth of photomicrographic slides, on the implantation of the human ovum, which was given by Prof. J. H. TEACHER, of Glasgow. He showed that fertilisation and implantation did not correspond to any part of the cycle in particular, but might occur at various points. There was not a long delay in fertilisation, but spermatozoa had a long viability. It seemed that rupture of the follicle nearly coincided with the insemination, and that fertilisation took place very shortly after that. Fertilisation had occurred within four or five days of the period being due, and as implantation did not occur for at least seven days—some declared it was ten days—it was not implantation of the ovum which stopped menstruation. That function was stopped, in his view, by fertilisation.

The thanks of the Congress were accorded Prof. Teacher for his demonstration.

During the Congress an instructive pathological exhibition was held under the control of Dr. Everard Williams. On Thursday members of the Congress dined together, and on Friday afternoon many operations were witnessed at a number of London hospitals.

Resolution.

On Wednesday the Congress agreed unanimously to the principle of a resolution to go to the Ministry of Health. On Friday the exact terms were approved, also unanimously, as follows:—

> "In the opinion of the British Congress of Obstetrics and Gynæcology, the most urgent requirement in connexion with the problem of sepsis is the provision of adequate accommodation for the reception and treatment of these cases in hospitals, supervised, wherever possible, by obstetric surgeons."

ROYAL SOCIETY OF MEDICINE.

SECTION OF UROLOGY.

A MEETING of this Section was held on April 23rd, Mr. CYRIL NITCH, the President, being in the chair. A discussion on

Bacterial Infections of the Urinary Tract

was opened by Prof. LEONARD DUDGEON, who confined his remarks to a few of the types of infection that might be encountered. (1) A special group of hæmolytic bacilli, isolated by himself, of which he had met many hundreds of cases. The condition and the bacillus strongly resembled that of paratyphoid at first sight. In a certain number of cases it had been possible to recognise the same organism, by serological tests, in the intestinal tract of patients suffering from urinary infection. The course of the infection differed markedly from that due to *B. coli* in the short acute course lasting for two or three weeks and then clearing up completely. If relapses occurred they were short. Patients suffering from this infection were more sensitive to vaccines than any others, and vaccine treatment produced immediate rise of temperature and return of severe clinical manifestations. Vaccine should never be given until the temperature had been normal for several days, and most cases recovered satisfactorily without it. (2) *B. coli.* Two strains of this bacillus were encountered—a hæmolytic variety, which accounted for 70 per cent. of cases in the male and 30 per cent. in the female, and a non-hæmolytic variety for which the sex percentages were exactly reversed. It was easy to immunise rabbits with the former but very difficult with the latter. The vast majority of colon bacilli were non-hæmolytic; the other kind was met with in certain cases of severe diarrhœa. It had long been believed that the intestinal canal was the origin of *B. coli* infections of other parts, and he had been able to prove this experimentally in a certain number of urinary cases. Treatment by vaccines was not satisfactory; it was very difficult to produce any degree of immune substances in the blood. An autogenous vaccine should be used, because of the two types; the hæmolytic type was more likely to be benefited by vaccines. If there was hypersensitivity to vaccine the dose should not be pushed or severe tissue damage might result. Animal experiments showed that if *B. coli* was held up in any part of the body it produced a suppurative lesion, as, for instance, if injected into serous sacs. In chronic cases it had been proved that coli abscesses were present in the kidney in those instances where the administration of vaccine caused rise of temperature. In those instances where he had investigated second attacks he had found that the organism was always identical with that causing the first attack. He therefore concluded that it had lain dormant somewhere in the urinary tract, although the urine might have cleared up completely. (3) *B. proteus.* Although some people regarded this as a non-pathogenic organism it might lead to the most acute infection, with the bacillus recoverable from the intestine and blood-stream. The urine in such cases was alkaline, containing a great deal of mucus, triple phosphates, and pus. A vaccine might be given when the acute stage was over and was sometimes successful. (4) *Staphylococcus albus.* The presence of this coccus in large numbers with pus in the urine was, in his experience, invariably associated with the existence of a calculus.

Dr. E. LEPPER described experimental work on the production of lesions in the kidney in rabbits by *B. coli*, in an attempt to account for the fact that intravenous injection of the organisms rarely caused serious damage unless there was coincident obstruction to the flow of urine. Compression of the ureter for 55 minutes resulted in necrosis of the cortex with multiple small abscesses, distension of the tubules, and inflammatory reaction. Even so short a compression as 15 minutes produced marked abscess formation, and if the animal were examined immediately, the pelvis was found to be distended with blood-stained urine and the renal vessels much dilated. The effect of the obstruction appeared to be produced by back pressure; the urine, being secreted and unable to escape, caused such distension of the veins that rupture occurred with extravasation of blood, containing bacteria, into the kidney substance. If no urine were secreted during the time of the experiment none of these results occurred. Injection of bacilli with no obstruction led to naked-eye lesions in 8 cases out of 50 only, with microscopic abscesses in 20 more. The process appeared to be one of bacterial embolism, setting up focal abscesses which might rupture into the tubules or on to the surface of the papilla and occasionally might cause infection of the whole pelvis. There was no known reason why the vessels of the papilla were more liable to embolism than those of the cortex.

Sir JOHN THOMSON-WALKER dealt with the diagnostic and therapeutic aspect of the problem, confining himself to those instances in which there had been no previous disease of the kidney. The acute case was ushered in by four or five days of prodromal symptoms, insufficient to cause the patient to seek advice. These took the form of irritability, loss of appetite, hypersensitivity to heat and cold, a little frequency of micturition, a little more flatulence or constipation or relaxation of the bowels than was usual. Then the attack began suddenly with frequency of micturition, in all degrees of urgency up to strangury. After a few hours there was rigor and rise of temperature. The urine was passed in small quantities, was cloudy, offensive, and might contain a little blood. There was distension of the bowel and constipation. More localising symptoms followed, generalised abdominal pain finally settling in the loin, sometimes taking the form of renal colic. A little rigidity and tenderness might be felt and a little enlargement of the kidney. If the condition was passing on to one of pyonephrosis there would be a swinging of the temperature, the local symptoms would be more severe, and the urine would become clear. But there might instead be difficulty in passing water, going on to retention, or pain, a sense of weight, and aching in the rectum with enlargement and tenderness of the prostate or distension of the vesiculæ seminales. Or localising symptoms might be entirely absent. The attack might last 14 or 21 days or drag on up to two or three months. Often there were exacerbations or recurrence of symptoms after complete subsidence. Uncommon symptoms were: (1) High temperature without other phenomenon. (2) Pain as the principal feature, either aching or severe in nature; such cases were liable to be diagnosed as appendicitis. (3) Renal colic, which might be just as acute with a descending ureteritis as with a descending stone. (4) Hæmaturia as the first symptom. In such a case the infective nature of the condition might be recognisable by the characteristic *B. coli* odour of the urine. (5) A sterile urine associated with a suppurative cortical nephritis. There would be high temperature, but few local symptoms, save an enlargement of the kidney due to perinephritis which might pass on to perinephritic abscess. The cause was usually the staphylococcus, and a history of boils or other staphylococcal skin infection could usually be traced. Of the chronic types Sir John Thomson-Walker considered three: (1) Recurrent pyelitis and cystitis. Of this variety there were two types, the acute attack which subsided but was followed six months or a year later by another and that by yet another. Between the attacks there were no symptoms save possibly a little irritability of micturition and slight rise of temperature. In the second type the infection recurred and the urine was sterile between the attacks. Some of these must be genuine reinfections; some were undoubtedly cases of infection of the seminal vesicles, but in the female it was difficult to see where the bacilli might lie dormant. (2) Chronic cystitis with quiescent pyelitis. These cases were very difficult as the ureteric catheter alone would show the real source of the trouble. The pyelitis might give rise to no symptoms at all. Out of 100 cases of cystitis taken at random, 42 had sterile kidney-urine, while the remainder had infection of the kidney. (3) Bacilluria without local symptoms. In many cases this was connected with chronic toxæmia, fibrositis, aches and pains, and stiff joints; many of the milder cases were classed as neurasthenia.

Treatment.

Certain prophylactic measures might be taken against infection from the bowel. The normal barriers preventing the passage of bacteria seemed to be an intact epithelium, with its mucous covering, the lymph nodes in the intestinal wall, and the glands along the colic vessels. An acute bacilluria might follow drastic purgation or Plombières treatment. Prolonged exposure to X rays and radium facilitated the passage of bacteria through the bowel wall, and possibly the removal of the normal appendix might do so also. Operations on the bowel should always be accompanied by the administration of urinary antiseptics. The antiseptics in use were salol, boric, and hexamine. It took some time to split hexamine in contact with an acid urine and the drug was excreted unchanged in cases where there was frequency of micturition. Moreover, the acutely inflamed bladder was unable to contain a very acid urine and the acidity must be limited. In cases with an acid urine Sir John Thomson-Walker had given up the use of hexamine and merely tried to soothe the bladder. The only antiseptic which could be used in an alkaline urine was methylene-blue, which was very mild. The intravenous injection of mercurochrome and methyl-violet, tried in America, had not fulfilled expectations. Lavage of the renal pelvis was the only cure in some cases, but they must be very carefully selected; cases of infection of the prostate or seminal vesicle or of obstruction of the lower urinary tract must be excluded, except in the pyelitis of pregnancy where the lavage seemed to help the condition. It was best in cases of persistent pyelitis.

Discussion and Reply.

Dr. **FOWLER WARD** asked Prof. Dudgeon how to distinguish between the two types of infection clinically in order to decide whether to give vaccine treatment or not.

Dr. J. A. **ANDREWS** mentioned the teeth and tonsils as sources of infection. Certain American experimenters had created cavities in the teeth of dogs and filled them with bacteria from the urine of patients and had succeeded in producing kidney lesions in a large percentage of cases.

Dr. **OLIVER HEATH** described a personal experience of cystitis from which he had attempted to determine the meaning of the symptoms experienced. The frequency of micturition was nature's way of producing frequent muscular contractions, with inflow of fresh blood, bearing antibodies, and of flushing out the bladder. He had found that the discomfort could be reduced to a minimum by drinking water in excess, while the withholding of fluid rapidly produced strangury. Treatment should be based on the sensations experienced as a guide to the *vis medicatrix naturæ*.

Mr. S. G. **MACDONALD** regarded acute infections by the *B. proteus* as rare; they were more usually a terminal stage in old stricture cases. He agreed as to the association of calculus with staphylococcal infection. A very important group not yet mentioned were the cases with sterile urine due to renal blockage. In his opinion surgical interference was only justified when there was this definite and persistent block. He asked where the splitting of hexamine took place as it did not seem to occur with a damaged kidney.

Mr. H. **EVERIDGE** inquired whether the estimation of the cholesterol content of the blood had any practical value in assessing the degree of infection.

Mr. **GRANVILLE HEY** described the case of a primipara three months' pregnant, who had no symptoms save a slight aching in the left loin and cloudy urine. A *B. coli* bacilluria was found associated with a calculus in the left kidney which was successfully removed. Certain American observers had demonstrated a direct continuity between the lymphatics of the right kidney and those of the ascending colon.

The **PRESIDENT** described a case of granuloma of the bowel with cystitis which had been completely cured by the intravenous injection of electrargol. Chronic *B. proteus* infections, in his experience, did well with vaccine treatment but the acute ones did not.

Prof. **DUDGEON**, in reply, said that the examination of a loopful of urine was insufficient; at least 10 c.cm. must be investigated before it was said to be sterile.

Sir **JOHN THOMSON-WALKER**, in reply, agreed that diuresis should always be employed as a method of treatment. He described a case of typhoid bacilluria cleared up by removal of a stone. The splitting of hexamine usually took place in the bladder, but it was a matter of time. The poor results obtained by its use in cases of enlarged prostate were due to the diuresis and great dilution of the urine, so that it is impossible to get a sufficiently high acidity for splitting, and to the condition of chronic interstitial nephritis, due to back pressure, so that less hexamine was excreted. Lavage would cure a certain percentage of cases, but might fail because the patient would not come long enough or regularly enough, or owing to the use of an insufficiently strong antiseptic, or the presence of a slight obstruction or small stone or pelvic dilatation. The worst type of case was a mixed infection with *B. coli* and *B. proteus*. Alkaline treatment encouraged the *B. proteus* while acids encouraged *B. coli*. If the patient happened to get an unconnected tonsil or throat infection the kidney condition became much worse at once, though the reason for this was not known.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES.

A MEETING of this Society was held in the rooms of the Medical Society of London on April 24th, Colonel L. W. HARRISON, the President, being in the chair.

TOXIC EFFECTS OF ARSENOBENZOL TREATMENT.

Mr. DAVID LEES opened a discussion on the toxic effects of arsenobenzol treatment and their prevention. He said that these toxic effects, both after intravenous and intramuscular injection, were produced in many ways, and many factors entered into consideration. The chief determining factors were the health of the patient prior to administration, the preparation of the patient, the drug used, the method of preparing it in solution, and the technique of administration. Physical exertion on the part of the patient, especially just before or after administration, might play a part in some of the reactions that were observed. The daily regulation of the bowels, again, was essential. With regard to the drugs, the "606" group were more toxic in general than the "914," and in the case of "606" it was very necessary to be careful and slow in administration. Indeed, in all the drugs given for the treatment of syphilis this slowness in administration was an important factor. He was a strong believer in dilute solutions, and he believed also in filtration. There was no doubt that any undissolved particles would open the way to accidents, which might be avoided by using completely soluble preparations. In a great many patients psychic reactions occurred at the first administration; they could be overcome usually by careful technique and by having the patient in the lying posture. The fact that the beginning of the injection caused pain to the patient might set up fainting and other minor reactions. Some patients, no matter what precautions were taken, would react adversely to either intravenous or intramuscular injections of arsenic. He discussed the various reactions, first those which occurred immediately on or after administration or within the first 24 hours, and then those which occurred later, up to a period of months. In the immediate reactions were included headache, vomiting, and diarrhœa. It was probable that more than one cause was present in the acute reactions which occurred after treatment with arsenobenzol. In his own experience, with care in the preparation of the drug, and especially in the dissolving of the drug, its filtration before use, and its slowness in administration, the incidence of the immediate reactions, both minor and major, was exceedingly small. Occasionally a sensitive patient was encountered and it was necessary to consider what steps should be taken to safeguard him. Mr. Lees found that with atropine desensitisation there was less likelihood of the patient having cardiovascular upset than with adrenalin. Of the reactions which occurred within 24 hours, skin eruptions, such as herpes and urticaria, were of little importance except as danger-signals. Special care should be taken to watch the kidneys of such patients. He spoke of vasomotor disturbances and gave particulars of cases.

With regard to later reactions, albuminuria often presented considerable difficulty. Was the albuminuria due to drug therapy or to syphilis? Only by waiting and watching could one possibly decide. One of the most interesting reactions was a gross exfoliating dermatitis. There were certain individuals who had a special idiosyncrasy of the skin to therapeutic irritants, and these showed undoubtedly a greater tendency to such a condition. From the experience of the past ten years he could not agree with the observation that the joint exhibition of arsenical and mercurial therapy predisposed to the onset of dermatitis. There was no actual proof that the dermatitis was due to over-excitation of the tissues by metallic arsenic, as suggested by McDonagh, and one was left to assume that it was due to hypersensibility to arsenic on the part of the patient. Patients made a slow and uninterrupted recovery unless complications set in. Of the complications the most dangerous was broncho-pneumonia, while others were peripheral neuritis and jaundice. If these complications could be avoided the prognosis was good. The drug most useful in the treatment of this condition was one of the sulphur compounds. In arsenical dermatitis the Wassermann test frequently became negative and might remain negative for a considerable time. Some workers had stated that such a patient never again showed any manifestation of syphilis, but this he believed to be very dangerous teaching. With regard to jaundice, many considered that this was due to the toxic action of arsenobenzol on the liver tissues. The predisposing factors were constipation and intestinal toxæmia. A very considerable number of the mild cases of jaundice one met with were not due to the salvarsan, although that might be a contributory factor, irritating, as it did, the mucous surface of the intestinal canal. It was a small matter for the inflammation to extend from the bowel through the biliary tract and set up a liver condition. In other words, salvarsan was more likely to injure the liver in a person infected with syphilis who, in addition, had an intestinal toxæmia and a possible predisposition to catarrhal jaundice. For treatment, rest in bed, evacuation of the bowels, and careful dieting were necessary, also the administration of alkalies in association with salicylate of soda, glucose given intravenously, and a diet rich in glucose. As a routine procedure he had recently been giving 50 c.cm. of glucose by the mouth to every patient half an hour before treatment with arsenic. This fortified the liver against the arsenic action, and he had had very few cases of catarrhal jaundice.

In conclusion, he emphasised the great necessity of careful preparation of the patient for administration and careful examination, especially of the urine, prior to administration. Next he emphasised care in dosage and in the technique of administration. Alcohol must be avoided throughout the whole course of the treatment. As to the amount and frequency of the drug, moderate doses should be given with a safe interval (one week), the average course of injections extending over eight weeks and the intervals of rest eight to ten weeks. Except in the early stage of the disease, heroic therapy by massive doses was not of so much value as moderate, safe, and prolonged dosage. Intramuscular administration was to be preferred to intravenous, especially in the later stages.

Dr. J. C. BUCKLEY said that in his clinic for the first two years, while the novarsenobenzol was of the old "Rochester Row pattern" not a single case of jaundice occurred, but during the last five years he had seen about 120 cases of jaundice, all of them very mild, except one, which proved fatal, the patient dying four and a half months after the administration of the drug. Of these 120 cases about 20 occurred among patients who had been put down as provisionally cured, having had a negative Wassermann for two years, and coming up every six months or so for a provocative dose or a test. As to dermatitis, the worst case he ever saw was long before "606" was introduced.

Dr. T. ANWYL DAVIES thought the most important lesson to be gathered was that the prophylactic against arsenical intoxication was intramuscular administration. In addition this had greater therapeutic value, and undoubtedly brought about a negative Wassermann sooner than did any other form of administration.

Dr. FOWLER WARD said that he had had formerly a good many cases of stomatitis, but now he made a practice the first week of giving arsenic and the second week of giving mercury intramuscularly with the arsenic, and since then very few cases of stomatitis had occurred.

Dr. D. N. NABARRO did not think that the psychic effect could be attributed to the drug itself. He found at Great Ormond-street that the same children week after week were sick after injections, and one nervous child used regularly to vomit before the injection was started. Recently he had been treating an adult case who had malaise and nausea after each intravenous injection of arsenic; he tried intramuscular injection of bismuth, and the patient stated that he had the same symptoms. Vasomotor disturbances were very rare in children, and when they did occur he thought they were due to too big a dose for the size of the child. Jaundice was also very rare among children. Some years ago he had one case of dermatitis occurring after a fourth injection of novarsenobenzol; the rash appeared on the first or second day after injection. Unfortunately, the child was not brought directly back to the hospital, but was taken first to an outside doctor. When later it came to the hospital the rash looked exactly like measles. The child was taken into a special observation ward and died.

Dr. H. C. SEMON had had one case of dermatitis, but never a case of jaundice. He was surprised that for the treatment of jaundice Mr. Lees did not suggest thiosulphate of soda; he had himself found that drug valuable.

Dr. C. H. MILLS said that in the earlier days of "606" patients were prepared as for a major operation and were starved. This course had been proved to be erroneous, and now patients were not starved; they were told to avoid physical exertion and the use of alcohol, and constipation was corrected. What was still wanted was some reliable test which could be applied in the out-patient department for the detection of intolerance.

The PRESIDENT said that he had previously ventured the opinion that the use of thiosulphate as a prophylactic might interfere with the therapeutic action of the remedy, but he now desired as the result of further work and consultation to retract that opinion. He also emphasised the effect of cold in increasing the predisposition to dermatitis.

Mr. LEES, in reply, urged that it was a very sound procedure to filter the solution in intramuscular therapy; it made for less pain and discomfort. He said it was more desirable to bring the patient's general health up to the highest possible level than to fill him up with salvarsan or its substitutes.

Clinical Cases.

Dr. H. M. HANSCHELL showed two clinical cases. The first was a Chinese seaman with ulcerating granuloma of the penis. The other was a European, about 30 years of age, who, four and a half months previously, had primary syphiloma on the prepuce, and the *Sp. pallida* was found. The Wassermann test was doubly positive; there were no secondary symptoms. After five intravenous injections at weekly intervals of stabilarsan, totalling 2·7 g., and five weekly injections of bismuth in glucose suspension, totalling 1 g., he developed severe purpura covering the trunk like a bright purple jersey. The liver became enlarged 3½ in. below the costal margin, the spleen 2 in. below. There was no fever or malaise, and the patient insisted on continuing his work, which was that of a carman. There was no albuminuria or glycosuria, and the Wassermann was still doubly positive. Treatment was suspended. A week previously he developed jaundice. The urine was of deep orange colour, there was no bile, no albuminuria, no glycosuria, the liver was not tender (though it was still 3 in. below the costal margin), the spleen was not palpable. The purpuric area was now staining brown. When first seen four and a half months previously there were abdominal pains. On palpation of the abdomen at that time no enlargement of liver or spleen was detected.

BRISTOL MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held at the University, Bristol, on April 8th, Dr. J. O. SYMES, the President, in the chair, when Mr. A. RENDLE SHORT read a paper on

Diagnosis of the Dyspepsias.

His observations were based on a series of 100 cases of non-malignant dyspepsia, all studied on a definite plan, all verified by operation, and mostly followed subsequently. The growth of accuracy in the diagnosis of dyspepsia was due to: (*a*) Better knowledge of physiology; (*b*) disregard of hæmatemesis as a diagnostic point; (*c*) watching the movements of the bowel by means of X ray screen; and (*d*) better classification. Knowledge of physiology had grown in several ways. It was now known that both the hypersthenic and the hypotonic types of stomach might exist in perfectly normal persons. In the former, the viscus emptied quickly; such persons were apt to have an excess of acid, and were "hungry folk." On the other hand, achlorhydria was not necessarily a sign of disease, any more than was visceroptosis. Again, we now knew that nervous reflex mechanism controlled the sphincters of the alimentary canal, so that delay in any one part might upset matters all along the line, and produce symptoms referred to a region distant from the actual site of the disease. Thirdly, minute lymph nodules were found especially along the lesser curvature of the stomach; these might ulcerate and bleed. Hæmatemesis might be the only symptom of disease, or there might be dyspepsia due to causes outside the stomach and duodenum, accompanied by dangerous bleeding, or finally there might be bleeding from a chronic ulcer. In the series, 1 in 3 of the gastric and duodenal ulcers were accompanied by bleeding, and 1 in 6 of the cases of appendicular dyspepsia. Mr. Short said that he classified dyspepsia as (1) functional, (2) organic, or (3) reflex. Functional did not mean hysterical, but disturbance of function, as with acute and chronic gastritis of alcoholism, dyspepsia of phthisis, anæmia, anorexia nervosa, and so forth—all these were the province of the physician. The reflex dyspepsias were (*a*) gall-bladder dyspepsia—flatulence and vomiting prominent, the vomiting coming especially after certain foods, alkalies did not help, there was often some gastric delay; (*b*) appendix dyspepsia, pain is usually not very severe, was *continuous*, but worse after food—often vomit without relief of pain; (*c*) undiagnosable reflex dyspepsia—pain and vomiting were not related to each other or to food.

Organic disease of the stomach or duodenum might give rise to several types of dyspepsia: (A) *Gastric ulcer.* These cases tended to show a definite sequence, thus—food, relief, pain, vomiting, relief. The relief following a meal tended to be rather over half an hour. The pain was severe and vomiting the rule. A test-meal was useless in diagnosis, but X rays might give great help. If later pain became continuous and was felt in the back, pancreatic involvement might be suspected. (B) *Duodenal ulcer.* Vomiting was less common, only half the cases showing it. Relief obtained by food lasted usually over an hour. The pain was severe. Test-meal was of little service, though hyperchlorhydria was the rule, but deformation of the skiagraphic duodenal cap was characteristic when seen. The stomach usually emptied rapidly, but this was a cause rather than a consequence of the ulcer. (C) *Duodenal ileus* might occur by itself or be a symptom of other disease. Flatulence and nausea were marked, vomiting was common, pain was not severe, and the relation to food was obscure. The skiagram might be definite, showing great delay and distension of the second and third parts of the duodenum; duodeno-jejunostomy brought about a cure. (D) *Periduodenal adhesions* might give rise to bad pain, even after taking water. Vomiting was usual, bleeding absent. The X rays showed gastric delay. (E) *Gastric cancer* was accompanied by great loss of appetite. Pain might be continuous. A test-meal might show nothing, but X rays might reveal a typical deformity. (F) *Pyloric stenosis*, hour-glass stomach, or leather-bottle stomach might account for dyspepsia. Mr. Short showed a number of skiagrams illustrative of his paper.

Discussion.

The PRESIDENT appeared to think that a better title would have been "Diagnosis of Surgical Dyspepsia"; only a small proportion of dyspepsia was amenable to surgery. A great proportion was due to worry. He viewed with distrust cases called appendicular dyspepsia. But he agreed with Mr. Short as to the anorexia of gastric cancer, and the small value of a test-meal.

Mr. C. A. MOORE asked what were the symptoms and pathology of duodenal ileus. He thought deformity of the duodenal "cap" rare. He related a case illustrative of the great difficulty of diagnosing gall-stone from duodenal ulcer. He agreed with Mr. Short that an atrophic appendix might be the cause of dyspepsia, and also that the dyspepsia might be accompanied by hæmatemesis.

Dr. D. A. ALEXANDER spoke of the value of long-kept records in diagnosis of dyspepsia, and instanced in this connexion cases of tuberculous adhesions.
